36 Chapter 36 Mammary Gland Health and Disorders

Dawn E. Morin

The efficient production of wholesome milk is the primary mission of a dairy farm. Mammary gland health is essential for maximizing milk production and farm profitability. It also ensures the safety and quality of milk and milk products and limits the use of antimicrobial agents on the farm. This chapter discusses the pathogenesis, diagnosis, treatment, and control of mastitis and other mammary gland disorders, with emphasis on dairy cattle.

The large size of new dairy operations, growing emphasis on the well-being of farm animals, and heightened public concern about antimicrobial residues in milk and antimicrobial resistance in pathogens present challenges for today's dairy producers. Competitive markets for high-quality milk and demand for “natural” milk products afford new opportunities. By providing expertise in prevention and treatment of udder health disorders, veterinarians can help producers address these challenges and enhance their opportunities for financial success.

36.1 ANATOMY AND PHYSIOLOGY OF THE MAMMARY GLAND

Knowledge of mammary gland anatomy and physiology is required to fully understand the pathophysiology of mammary gland disorders. The bovine udder comprises four mammary glands, each with its own teat. The milk-synthesizing cells of the mammary gland, called *mammary epithelial cells,* are arranged in hundreds of alveoli, each with a central lumen. In normal lactating glands, tight junctions between the epithelial cells provide an impermeable barrier that prevents molecules and ions from diffusing between blood and milk.

Nutrients required for milk synthesis are delivered to the mammary gland by the circulatory system and transported into the epithelial cells or directly into the alveolar lumen. Major milk constituents, such as casein, lactose, and fat, are synthesized within the epithelial cells and secreted into the lumen, where they combine with other constituents to form milk. A portion of the milk synthesized between milkings (the *cisternal fraction*) drains from the alveoli through a series of progressively larger ducts to be stored in cisterns in the gland and teat; however, most of the milk (the *alveolar fraction*) remains in the alveoli until milk ejection occurs.[1]

When the teats are manipulated at milking time, a neurohormonal reflex, triggered by pressure-sensitive receptors in the teat skin, causes the pituitary gland to release *oxytocin* into the bloodstream.[2] Milk is ejected when myoepithelial cells surrounding the alveoli and adjacent ducts contract in response to binding of oxytocin. When the resistance of the teat canal (also called *streak canal*) is overcome by pressure of milk in the teat or by milking or suckling, milk is expelled through the teat orifice.[2] Activation of the sympathetic nervous system, as occurs during stress or excitement, can inhibit the release of oxytocin from the pituitary gland or the binding of oxytocin to myoepithelial cells, thus preventing milk ejection.[3]

As with cattle, South American camelids (SACs; llamas, alpacas) have four mammary glands, called *quarters*. In contrast, sheep, goats, and horses have only two mammary glands, called *halves*. In horses and SACs, each mammary gland is composed of two distinct lobes.[4,5] Horses and SACs also have relatively small teats and limited cisternal storage capacity compared with ruminants. Otherwise, mammary gland anatomy and physiology are similar among livestock species.

36.2 DEFENSE MECHANISMS OF THE MAMMARY GLAND

A host of physical, cellular, humoral, and chemical defense mechanisms protect the mammary gland against infection. These defense mechanisms enable the mammary gland to resist microbial invasion, inhibit microbial growth, destroy and remove microbes, neutralize toxins, and resist tissue damage during inflammation.

36.2.1 Teat Canal

The teat canal and surrounding musculoelastic tissue provide the primary physical barrier to microbial invasion and also prevent leakage of milk between milkings.[6,7] The teat canal is a narrow, longitudinally folded cylinder lined with stratified squamous epithelium. The tortuous shape of the canal provides physical protection against infection, as does protein-rich *keratin,* which is continually produced by the epithelial cells and lines the canal. Keratin physically plugs the teat canal and traps invading microbes, which are then expelled with sloughed keratin at milking time. Keratin also contains fatty acids and proteins that have bacteriostatic or bacteriocidal effects in vitro,[8,9] although their role in mammary gland defense is uncertain. Loss of keratin greatly increases the risk of intramammary infection.[10]

Management practices and the cow's physiologic state influence teat function and mastitis resistance For example, the integrity of the teat canal is compromised for up to 2 hours after milking while the elastic fibers surrounding the canal recoil and keratin begins to be renewed.[6,11] Therefore, it is recommended that cows be fed after milking, to keep them standing and to minimize exposure to pathogens while the teat canal recovers. When a cow is dried off at the end of lactation, the teat canal does not fully fill with keratin for days to months. A delay in keratin plug formation is associated with an increased risk of intramammary infection.[12,13] When antibiotics are infused into the teat, full insertion of the cannula disrupts the keratin and can transport microorganisms from the teat canal or skin into the teat cistern. Therefore, the “partial-insertion” method of administering antibiotics, whereby the cannula is inserted only 2 to 3 mm into the canal, is recommended.[14] Using the partial-insertion method to infuse antibiotics at dry-off can reduce the incidence of intramammary infection or clinical mastitis during the dry period.[14,15]

1112

1113

Callosity (hyperkeratosis) of the teat end and abrasion of the teat orifice epithelium increase the risk of intramammary infection.[16,17] Trauma to the teat end compromises teat canal function and predisposes to infection. Trauma can occur when a cow steps on her teat or as a consequence of the milking process. Ineffective pulsation, excessive milking vacuum, or poorly fitting teat cup liners can damage teat tissue during milking.[18] Air admission into the milking cluster, as occurs with liner slips, can cause reverse-pressure gradients that propel bacteria-laden milk droplets up through the teat canal into the teat cistern.[19] Even the shape of the teat end and length and diameter of the teat canal influence infection risk; short, wide teat canals and flat or inverted teat ends predispose to mastitis, as does teat canal protrusion.[7,20,21]

Because of the importance of the teat in mammary gland defense, dairy producers should routinely monitor teat condition and use a combination of genetic selection and management practices to promote teat health and function. *Teat Club International,* a group of researchers, veterinarians, and udder health advisors, has developed a standard method for scoring teat condition; the method and images are published on an educational CD available through the National Mastitis Council (NMC; www.nmconline.org).

36.2.2 Cellular Defense Mechanisms

Once microbes have breeched the teat canal, leukocytes and mammary epithelial cells constitute the next line of defense. Milk from healthy mammary glands contains a low concentration (<100,000/mL) of cells, the majority of which are macrophages. However, when microbes are detected, macrophages and epithelial cells release cytokines and chemokines that trigger an influx of neutrophils.[22,23] The rapidity and extent of neutrophil influx are critical determinants of infection outcome.[24,25] Neutrophils are the predominant cells in mastitic milk, with concentrations often exceeding 1 million/mL during acute infection. Macrophages, lymphocytes, and epithelial cells are present in much lower concentrations, with the total cell concentration referred to as the *somatic cell count* (SCC).

36.2.2.1 NEUTROPHILS

Neutrophils are critical for eliminating mastitis-causing pathogens from the milk. An effective neutrophil response to infection includes four functions: recruitment, phagocytosis, intracellular killing, and apoptosis. Deficiencies in any of these functions can increase the severity or duration of mastitis.

36.2.2.1.1 Neutrophil Recruitment

Neither microbes nor microbial toxins are strongly chemotactic for bovine neutrophils. Therefore, the presence of organisms in the milk does not effectively stimulate neutrophil recruitment.[26] Initial recruitment depends on release of chemotactic factors from macrophages and epithelial cells. Two potent chemoattractants for bovine neutrophils are interleukin-8 (IL-8) and complement factor C5a.[27,28] However, other proinflammatory cytokines, including tumor necrosis factor alpha (TNF-α), interleukin-1 beta (IL-1β), and granulocyte-monocyte colony-stimulating factor (GM-CSF), also attract bovine neutrophils and may play a greater role in recruitment than previously recognized.[23]

Circulating blood neutrophils must adhere to the vascular endothelium before migrating into the milk. Vascular neutrophils in the marginal pool loosely bind and roll along the endothelium, using a surface adhesion molecule called CD62L (L-selectin). In response to proinflammatory mediators, endothelial cells express surface receptors that cause neutrophils to upregulate expression of the β_2-integrin adhesion complex CD11b/CD18. The CD11b/CD18 complex firmly anchors neutrophils to vascular and intercellular adhesion molecules (VCAMs and ICAMs). Once bound, neutrophils migrate between the endothelial and mammary epithelial cells into the milk *(diapedesis),* traveling along the chemotactic gradient to the site of infection.[23,29] Both the speed of recruitment and the number of neutrophils recruited influence microbial clearance.[22,26] In fact, the chemotactic responsiveness of neutrophils in vitro can distinguish cows that are “high responders” or “low responders” to intramammary infection and predict the severity and outcome of mastitis.[30]

36.2.2.1.2 Neutrophil Phagocytosis

Neutrophils become activated during diapedesis and chemotaxis. Activation results in upregulation of surface receptors that facilitate phagocytosis. These receptors recognize and bind microbial cell wall components or specific opsonins. Expression of CD14 receptors enables neutrophils to bind bacterial

lipopolysaccharide (LPS) in the presence of LPS-binding protein (LBP); this binding facilitates nonopsonic phagocytosis of gram-negative bacteria.[31] At the same time, soluble CD14 (sCD14) is shed into the milk, where it neutralizes free LPS and binds to epithelial cells, enhancing chemoattractant release.[26] The most important neutrophil receptor for opsonic phagocytosis is the *Fc receptor,* which binds the Fc region of immunoglobulins (Ig), particularly IgG_2 and IgM, enabling the phagocytosis of antibody-coated pathogens.[32,33] Complement component 3b is also opsonic for bovine neutrophils.[28]

Receptor binding stimulates the neutrophil to extend pseudopods and engulf the adhered pathogen into a phagosome. The phagosome fuses with cytoplasmic secretory granules to form an intracellular vesicle (phagolysosome), where degranulation and microbial killing take place. Unfortunately, neutrophils in milk are less efficient at phagocytosing and killing microorganisms than are neutrophils in blood. In milk, neutrophils engulf fat globules and casein, which reduces subsequent pseudopod formation as well as intracellular killing capacity.[26] This may explain why such a large number of neutrophils must be recruited.

36.2.2.1.3

Neutrophil Antimicrobial Systems

Two general antimicrobial systems, designated "oxygen (O_2) dependent" and "O_2 independent," contribute to neutrophil-mediated killing of microorganisms. Ingestion of microorganisms leads to an increase in oxygen consumption and generation of a variety of reactive oxygen species (ROS), such as superoxide anion and hydrogen peroxide; these ROS interact to form hydroxyl radical and singlet oxygen, which are strongly bactericidal.[26,29] Myeloperoxidase, which is released from cytoplasmic granules within the neutrophil, stimulates production of other bactericidal species, such as hypochlorite.[34] This O_2-dependent process is called the "respiratory burst" or "oxidative burst." Reduced ROS production by neutrophils in milk is associated with increased severity of *Escherichia coli* mastitis. In fact, cows can be classified as low or high responders to *E. coli* mastitis on the basis of preinfection ROS-generating capacity.[34]

Neutrophil granules contain cationic peptides called *bactenecins* and *defensins,* which have broad-spectrum antibacterial and antifungal activities.[22,35] These proteins, along with lactoferrin, hydrolytic enzymes, and a variety of other substances contained in neutrophil granules, contribute to O_2-independent killing of engulfed pathogens.

36.2.2.1.4

Neutrophil Apoptosis

1113

Prompt elimination of neutrophils that have completed their antimicrobial functions is necessary to avoid release of cellular contents that can damage host tissue. Neutrophil elimination is accomplished by programmed cell death *(apoptosis),* followed by phagocytosis. Apoptosis fragments the neutrophil into small, membrane-bound bodies that are easily phagocytosed and removed by macrophages.[26,36]

1114

36.2.2.2

MACROPHAGES AND LYMPHOCYTES

Macrophages are the predominant leukocytes in normal milk but are greatly outnumbered by neutrophils during mastitis. As with neutrophils, macrophages ingest and kill microorganisms.[37] They appear to be particularly important in chronic intramammary infections and during involution (dry-off) of the mammary

gland. Macrophages process and present antigen to T lymphocytes, enabling them to secrete cytokines, activate B lymphocytes, and exert cytotoxic, suppressor, and memory functions.[38] In milk, $CD8^+$ (memory, cytotoxic, and suppressor) lymphocytes predominate over $CD4^+$ (helper) lymphocytes.[39] However, percentages of lymphocyte subclasses change with stage of lactation[39] and are impacted by the presence and duration of intramammary infection.[40] Milk also contains γδ T lymphocytes, which may help regulate the inflammatory response or heal damaged epithelial cells,[29] and natural killer (NK) cells, which are cytotoxic.[38] B lymphocytes recognize specific antigens and differentiate into antibody-secreting plasma cells and memory cells.

36.2.2.3 EPITHELIAL CELLS

Although leukocytes are considered the main defensive cells in the mammary gland, epithelial cells are recognized as mediators of the early, innate immune response to infection. Toll-like receptors, which are found on epithelial cells, recognize conserved bacterial components, such as LPS on gram-negative bacteria or lipotechoic acid on gram-positive bacteria. Binding leads to a cascade of events that causes production and release of proinflammatory cytokines and chemokines.[22,41] Cytokine production is lower and less persistent in response to lipotechoic acid than LPS, which may help explain why gram-positive intramammary infections tend to be more persistent than gram-negative infections.[42] Epithelial cells are also a source of antimicrobial proteins, such as β-defensins. As research continues, additional roles for epithelial cells in mammary gland defense will probably be identified.

36.2.3 Noncellular Defense Mechanisms

36.2.3.1 IMMUNOGLOBULINS

Immunoglobulin concentrations are low in normal milk but rise in response to intramammary infection; the rise partly results from local Ig production but mostly from increased permeability of vascular endothelial cells and mammary epithelial cell tight junctions, which allows an influx of plasma Ig (and other plasma proteins) into milk. Influx of opsonizing Ig (IgM and IgG_2 in cattle) enables efficient phagocytosis of microorganisms by neutrophils.[32,33,43] Nonopsonizing Ig (IgG_1 and IgA in cattle) have other beneficial functions, such as neutralization of bacterial toxins, agglutination of bacteria, and prevention of bacterial adherence to epithelial cells. Immunoglobulins in milk also mediate antibody-dependent cell-mediated cytotoxicity by leukocytes.[38,44]

36.2.3.2 LACTOFERRIN AND OTHER ANTIMICROBIAL PROTEINS

Lactoferrin is an iron-binding glycoprotein produced by mammary epithelial cells and found in neutrophil granules.[45] Lactoferrin concentration is low in normal milk but increases substantially during the dry period and in response to intramammary infection.[22] By sequestering iron, lactoferrin prevents multiplication of iron-dependent microorganisms, such as coliform bacteria.[46] Lactoferrin plays a more general role in mammary gland defense by modulating granulopoiesis, leukocyte trafficking, lymphocyte cytotoxicity, and other immune functions. By disrupting bacterial cell membranes, it is also bactericidal.[22,47]

Lysozyme and lactoperoxidase are other antimicrobial proteins that play more minor roles in mammary gland defense.[38] Xanthine oxidase, found in milk fat globules, catalyses the formation of nitric oxide, which also plays a role in mammary gland defense.[22]

36.2.3.3 CYTOKINES

Cytokines regulate the activity of cells involved in nonspecific and specific immune responses. Many cytokines are produced in response to intramammary infection and influence the signs, severity, and outcome of mastitis. The origins, actions, and interactions of these proteins are too extensive to cover in detail. However, of major importance are the interleukins (ILs), interferons (IFNs), TNF-α, and colony-stimulating factors (CSFs).[48] Macrophages, T lymphocytes, and epithelial cells are the main producers of these cytokines. The cytokines interact with membrane receptors on target cells to stimulate release of leukocytes from bone marrow, enhance recruitment and activation of neutrophils, influence antibody production by B lymphocytes, direct the inflammatory response to infection, and in some cases, induce toxic shock.[29,38] Differences in cytokine profiles elicited by *Escherichia coli* and *Staphylococcus aureus* may help explain why *S. aureus* mastitis is more persistent than *E. coli* mastitis.[48]

Recombinant cytokines (e.g., IL-2, G-CSF, GM-CSF, IFN-γ) have been investigated as preventative[49,50] or therapeutic[27,51,52] agents for mastitis and as vaccine adjuvants.[53] Although these cytokines have been effective in some in vitro and in vivo studies, none has proved sufficiently safe or practical for commercial use.[54]

36.2.4 Defense Mechanisms in the Periparturient Period

Mammary gland defense mechanisms are greatly reduced in the periparturient period, making cows most vulnerable to mastitis at that time. Indeed, both the incidence and the severity of mastitis are higher in the periparturient period than at other times.[29,55–57] Neutrophil functions, particularly chemotaxis and intracellular killing, are impaired in periparturient cows, as is phagocytosis by macrophages. The immunosuppression accompanying parturition is partly caused by a high circulating cortisol concentration, which impairs neutrophil margination and recruitment. Neutrophils of periparturient cows also undergo apoptosis more rapidly than do neutrophils of cows in later lactation, and early onset of apoptosis reduces phagocytic and intracellular killing activity.[26] Low circulating concentrations of insulin-like growth factor 1 (IGF-1) in periparturient cows may reduce neutrophil viability and impair cytokine secretion.[56] Because a cow's ability to resist microbial challenge is reduced during the periparturient period, producers must pay special attention to the housing and management of periparturient cows.

36.3 INTRAMAMMARY INFECTION AND MASTITIS

The importance of mammary gland defense mechanisms in protecting against or limiting the effects of intramammary infection cannot be overstated. When pathogens traverse the teat canal and multiply in the milk, an inflammatory response is initiated, which results in mastitis (inflammation of the mammary gland). If cellular and noncellular defense mechanisms combat the infection rapidly and effectively, mastitis will be mild and transient. However, when defense mechanisms are compromised (e.g., during periparturient period) or when the pathogen is

able to evade normal defenses (e.g., resist phagocytosis or intracellular destruction), severe or chronic mastitis may develop. The intensity of the inflammatory response determines whether mastitis is subclinical or clinical.

With *subclinical mastitis,* the inflammatory process does not result in visible abnormalities in the milk, mammary gland, or cow. However, milk production is reduced and milk composition altered.[58] With *clinical mastitis,* milk from the affected quarter is visibly abnormal, the gland itself may appear inflamed, and the cow may exhibit a drop in milk production and general signs of illness. Although mastitis can develop in response to trauma, the vast majority of mastitis episodes are caused by intramammary infection. It is preferable to promote mastitis resistance and limit exposure to pathogens than to combat mastitis once it has developed. However, episodes of mastitis will occur even in well-managed herds.

36.3.1 Detection of Subclinical Mastitis

36.3.1.1 SOMATIC CELL COUNT

Subclinical mastitis is the predominant form of mastitis in cattle and other livestock. A consistent finding with subclinical mastitis is an increase in the SCC of the milk. The SCC can be measured in milk from an individual quarter (QMSCC) or milk composited from all four quarters (CMSCC). In either case, SCC greater than 100,000/mL is consistent with inflammation (mastitis). However, inflammation is not synonymous with intramammary infection. Milk from cows with intramammary infection usually has an SCC substantially higher than 100,000/mL because of neutrophil recruitment. The CMSCC is lower than the QMSCC because milk from the uninfected quarters dilutes the cells from the infected quarter.

Although intramammary infection is the most important determinant of SCC, SCC can be influenced by stage of lactation and milk production. For example, colostrum and milk produced during the first week after calving often have higher SCC than milk produced later.[59,60] Some investigators have also observed an increase in SCC during late lactation.[59] Findings in early and late lactation may be confounded because intramammary infection is common at those times and milk production is relatively low, which concentrates the cells.[61] Any disease that causes a marked drop in milk production, such as abomasal volvulus or traumatic reticulopericarditis, may cause an increase in SCC because of concentration.

The SCC of milk can be quantified by direct microscopic observation or by use of a Coulter counter. However, most commercial laboratories use a fluoro-opto-electronic (Fossomatic) cell counter, which can accurately measure SCC in preserved or frozen milk.[62] In the United States, many dairies subscribe to monthly CMSCC testing of all lactating cows. The CMSCC is typically reported as linear score (LS), a logarithmic conversion of SCC calculated as follows: $LS = \log_2 (SCC/100) + 3$. Conversion to LS achieves a normal distribution and linear association with milk yield loss (see section on economics).

Because SCC can remain high after intramammary infection resolves and can vary during the course of an infection, the accuracy of a single QMSCC or CMSCC for detecting infection is compromised.[59] A SCC threshold of 200,000 or 250,000/mL is usually recommended for cattle; cattle with SCC below the threshold are assumed to be free of intramammary infection, and cattle with SCC above the threshold are assumed to have intramammary infection. Unfortunately, no SCC threshold is perfect. The lower the threshold, the higher is the sensitivity (more infected glands are detected) and lower the specificity (more uninfected glands are classified as infected). Increasing the threshold improves specificity (more uninfected glands are correctly classified) but reduces sensitivity (more infected glands are missed). The choice of threshold therefore

depends on the purpose of testing. For example, if it is important to identify all infected cows so they can be managed in a certain way (segregated, culled, or treated), a low SCC threshold should be used to select animals for culture so infections are not missed. However, when screening cows to determine the types of pathogens causing high SCC in a herd, use of a higher SCC threshold to select animals for culture will reduce the chance that cultures will yield no growth.

The predictive value of SCC is impacted by the prevalence of intramammary infection in a herd. For example, SCC values above a given threshold are more likely to predict intramammary infections correctly in a herd with a high prevalence of mastitis than in a herd with a low prevalence of mastitis. In contrast, SCC values below a given threshold are more likely to predict healthy glands correctly in a herd with a low prevalence of mastitis than in a herd with a high prevalence of mastitis.[63] Therefore, knowing the approximate prevalence of mastitis in a herd is helpful when interpreting SCC data.

36.3.1.2

CALIFORNIA MASTITIS TEST

A rapid, inexpensive alternative to SCC testing is the California Mastitis Test (CMT). With the CMT, 2 to 3 mL of milk from each quarter of the mammary gland is stripped into individual cups of a hand-held paddle. A reagent is added to lyse the cells and agglutinate cellular proteins, resulting in thickening (gelling) of the mixture.[64] The degree of gelling is subjectively scored using a five-point scale; a score of 0 (negative) corresponds to SCC less than 200,000/mL.[64] Although qualitative, progressively higher CMT scores correspond to progressively higher ranges of SCC.

The CMT is impractical for routine monitoring of mastitis prevalence in a herd but can be a useful tool for screening individuals, such as fresh cows, for possible infection and selecting quarters for culture.[65,66] As with the SCC, the CMT is not a perfect test for intramammary infection. The optimal threshold will depend on the stage of lactation and objective of testing.[60]

Hand-held SCC counters are available for use at cow-side. However, the need for exact SCC quantification (vs. qualitative CMT results) must be weighed against cost to determine if such a purchase is warranted. Advantages of cow-side SCC counters and the CMT are that they provide immediate results and can be used to assess individual quarters, whereas monthly CMSCC provides infrequent data for the cow as a whole. A test strip that simultaneously detects cells and actively respiring bacteria in milk (V Strip 2, GeneBact Animal Health) is available in the United States, but the utility and acceptance of this test remain to be determined.

36.3.1.3

ELECTRICAL CONDUCTIVITY

An alternative method of subclinical mastitis detection is measurement of electrical conductivity of the milk. Electrical conductivity of normal milk is approximately 4.0 to 5.5 ms/cm^2 at 25° C. With mastitis, increases in sodium and chloride concentrations and a reduction in potassium concentration in the milk result in an increase in electrical conductivity.[67] An advantage of electrical conductivity over SCC is that conductivity can be measured automatically while cows are being milked, using sensors in the milking system. It is therefore adaptable to robotic milking systems.[68] Unlike CMSCC testing, which is performed monthly, electrical conductivity can be measured at each milking, thus allowing changes to be detected early. Results can be downloaded and archived on a computer and calculations performed. Mastitis detection can be based

on an absolute increase in conductivity or on interquarter ratios or differences in conductivity, with a combination of absolute and interquarter thresholds being most sensitive.[67]

The median sensitivity of electrical conductivity for detecting intramammary infection in 41 studies was 75% and the median specificity 95%.[67] However, in herds with a low prevalence of mastitis, the predictive value of a single or multiple positive tests can be much less than 60%.[69,70] Variations in electrical conductivity can occur with transient intramammary infections that do not require treatment and for reasons other than mastitis. Therefore, treatment should not be initiated on the basis of electrical conductivity results. As with SCC, electrical conductivity is simply a tool to assist in mastitis detection. Dairy producers must use electrical conductivity data along with other automated data (milk production, milk temperature, milk color, pedometry data) and physical examination findings to identify cows for monitoring or further testing. Although hand-held electrical conductivity meters are available, they generally perform poorly compared with the CMT for cow-side detection of subclinical mastitis.[71]

36.3.1.4 OTHER SUBCLINICAL MASTITIS INDICATORS

A variety of milk compositional changes accompany subclinical mastitis besides the increase in SCC. These include reduced casein, lactose, and α-lactalbumin concentrations; an influx of sodium, chloride, and plasma proteins; increased proteolytic and lipolytic activity; an increase in lactoferrin concentration and enzyme activities; and a rise in pH.[58] As a result of permeability of mammary epithelial cell tight junctions, potassium, lactose, casein, α-lactalbumin, and other mammary gland—derived substances move from milk into plasma. Many of these changes can be used as indicators of subclinical mastitis. Among the more common milk tests are those that detect albumin, sodium, chloride, lactose, or adenosine triphosphate (ATP) concentration; *N*-acetyl-β-D-glucosaminidase (NAGase) activity; antitrypsin activity; or pH; plasma tests detect α-lactalbumin, casein, or lactose concentration.[58,71–75] Milk concentrations of the acute-phase proteins amyloid A and haptoglobin are also used to distinguish healthy quarters from those with subclinical mastitis.[71,75] To date, none of these tests has proved sufficiently more accurate or convenient than SCC, so they are used mainly in research.

36.3.2 Detection of Clinical Mastitis

Clinical mastitis results in obvious abnormalities of the milk, mammary gland, or cow and is easier to recognize than subclinical mastitis. Most episodes of clinical mastitis are mild to moderate in severity. With *mild* clinical mastitis, milk from the affected quarter is abnormal in color, viscosity (watery, thick), or consistency (contains flakes or clots of inflammatory material). In *moderate* cases the affected mammary gland is noticeably inflamed (swollen, firm, warm, red, painful), and milk production may be somewhat decreased. With *severe* clinical mastitis, milk and mammary gland changes are accompanied by systemic illness. Systemic signs may include decreased feed intake or milk production, lethargy, depression, tachypnea, enophthalmos, weakness, recumbency, or low-volume diarrhea that may contain mucus or blood. Physical examination of the cow often reveals fever, tachycardia, decreased rate or strength of rumen contractions, prolonged skin tent or capillary refill time, tacky mucous membranes, or cold extremities.[76–79] Hypothermia may precede death in fatal cases. Occasionally, *gangrenous* mastitis occurs, in which case the skin of the mammary gland or teat may be cold, black, or crepitant, and gas may be expelled when milking the teat.

The severity of clinical mastitis influences the choice of treatment, as well as the prognosis, so efficient detection of clinical mastitis and determination of severity are critical. Detection of clinical mastitis is

accomplished by stripping foremilk onto the floor of the milking parlor at each milking. Milk that is grossly abnormal must be discarded or fed to calves and must not enter the bulk tank. Grossly abnormal milk generally has a very high SCC and altered composition, so immediate exclusion from the bulk tank helps to protect milk quality. Currently, no automated methods reliably detect clinical mastitis in the milking parlor, although such tests are being sought for robotic milking systems.

Milking personnel should routinely check mammary glands for signs of inflammation while cows are in the milking parlor. When cows with abnormal milk or an inflamed mammary gland have reduced milk yield or appear to be systemically ill, they should be examined promptly and systematically to determine mastitis severity and appropriate actions. Relevant farm staff must therefore be trained in assessment of attitude, rectal temperature, hydration status, and ideally, rumen motility.

Resolution of clinical signs is not synonymous with resolution of intramammary infection. Clinical signs may persist for a time after the pathogen has been eliminated, as often occurs with *E. coli* mastitis, or infection may persist after clinical signs have resolved, as with *S. aureus* mastitis. Regardless, clinical mastitis is always followed by a period of subclinical inflammation. If the infection has resolved, SCC usually returns to normal within 2 weeks.[80] Persistent elevation in SCC suggests chronic intramammary infection, which can be accompanied by recurrent bouts of clinical mastitis. Therefore, monthly CMSCC and periodic CMT are useful tools for assessing the likelihood of cure after clinical mastitis.

36.4 CONTAGIOUS VS. ENVIRONMENTAL MASTITIS

Mastitis pathogens have traditionally been categorized as “contagious” or “environmental” based on the primary reservoir of infection and mode of transmission. With the advent of new methods of strain typing, this method of categorization clearly is oversimplistic. Within both pathogen groups are strains that vary in contagiousness. The traditional categorization still provides a reasonable basis for investigating risk factors and initiating control programs in problem herds. However, if control measures do not achieve expected results, strain typing of pathogens can help to identify an atypical reservoir(s) of infection. The next two sections provide general information about the epidemiology and control of contagious and environmental mastitis. Specific pathogens are discussed in more detail in later sections.

36.4.1 Contagious Mastitis

Infected mammary glands are the predominant reservoirs of contagious mastitis pathogens. Transmission occurs when milk from an infected gland contacts the teat of an uninfected gland during the milking process. The teat cup liners of the milking cluster are important fomites if infected cows are milked before uninfected cows. Other fomites include the hands of the milking personnel and towels used to wash or dry the teats of multiple cows. Once pathogens have been deposited on the teat skin, the gland is at risk of infection, especially when teat defense mechanisms are compromised. In some cases, abrupt vacuum fluctuations within the milking cluster (reverse-pressure gradients) can propel contagious pathogens from the milk of an infected gland into the teat canal of an uninfected gland.[19]

1116

1117

Streptococcus agalactiae and *Staphylococcus aureus* are major contagious mastitis pathogens that cause persistent elevation in SCC and reduction in milk yield. *Corynebacterium bovis* is a minor contagious mastitis pathogen with a lesser impact on SCC and milk yield. Infection with these three pathogens can be controlled by implementing a five-point mastitis control program consisting of (1) postmilking germicidal teat disinfection *(postdipping),* (2) antibiotic treatment of all quarters of all cows at dry-off (“blanket” dry-cow antibiotic

therapy), (3) culling of chronically infected cows, (4) prompt recognition and treatment of clinical mastitis cases, and (5) proper use and maintenance of the milking machine.[81] Together, these measures reduce both the incidence and the prevalence of infection. *Mycoplasma bovis* and other *Mycoplasma* species are usually categorized as contagious mastitis pathogens even though they colonize body sites other than the mammary gland (see section on *Mycoplasma* mastitis). This is because once intramammary infection is established, *Mycoplasma* spreads among cows and glands in a contagious manner.

36.4.1.1 POSTMILKING GERMICIDAL TEAT DISINFECTION

Postdipping is the key to preventing new contagious mastitis infections.[82,83] Postdipping kills pathogens deposited on the teat skin during the milking process before they colonize the teat orifice and invade the gland. A variety of germicides are effective, with iodine-based (0.1% to 1.0%) dips the most common. However, not all products are equally effective. To determine if a particular germicide has been scientifically tested and proven effective, practitioners can consult the *Summary of Peer Reviewed Publications on Efficacy of Pre-milking and Post-milking Teat Disinfectants Published since 1980,* which is updated regularly by the NMC and available in the NMC annual meeting proceedings or at www.nmconline.org

Even teat dips of proven efficacy may fail to control mastitis if they are stored or handled improperly or not used consistently. Each teat of every lactating cow must be dipped after each milking; discontinuing dipping during cold weather or when mastitis appears to be under control is likely to result in reemergence of mastitis. Poor coverage of teats with dip is a common cause of postdipping "failure." In particular, spraying the teats, rather than using a dip cup, often results in incomplete coverage. When investigating a contagious mastitis problem, the postdipping process must be observed, rather than simply questioning the producer.

36.4.1.2 ANTIBIOTIC TREATMENT OF DRY COWS

Blanket dry-cow antibiotic therapy is the most effective way to resolve contagious mastitis infections once they occur.[82] *S. agalactiae* and *C. bovis* are susceptible to the antibiotics marketed for dry cows in the United States; cure rates approaching 100% can be expected. *S. aureus* infections are more resistant to antibiotic treatment for several reasons (see section on *S. aureus* mastitis). However, the cure rate for *S. aureus* mastitis is higher when antibiotics are administered during the dry period than during lactation. Cows with chronic *S. aureus* mastitis, especially mastitis that fails to resolve after dry-cow antibiotic therapy, are candidates for culling. *Mycoplasma* species are resistant to the antibiotics available for use in dry cows in the United States, so blanket dry-cow antibiotic therapy will not reduce the prevalence of infection. To eliminate chronic *Mycoplasma* infections, cows must be culled.

Selective dry-cow antibiotic therapy is an appealing alternative to blanket therapy because it reduces antibiotic treatment of uninfected glands. However, common selection criteria (CMT score, lactation average SCC, clinical mastitis history) are imperfect indicators of infection status. When a high CMT or SCC threshold is used, many infected glands will go untreated. When a low CMT or SCC threshold is used, many uninfected glands will be treated. Even milk cultures fail to detect a portion of chronic infections. Therefore, in herds with a high prevalence of contagious mastitis, or with risk factors favoring contagious mastitis transmission, blanket dry-cow antibiotic therapy is prudent. Selective dry-cow therapy also fails to protect untreated glands against new infections in the early dry period.[84]

36.4.1.3 OTHER CONTAGIOUS MASTITIS CONTROL MEASURES

Individual cloth or paper towels (one per cow) should be used to prepare teats for milking. Milking personnel should wear gloves and wash them frequently. An automated back-flushing system can be installed to disinfect milking clusters between cows. A milking order can be established, in which uninfected cows are milked before infected cows. Milking fresh heifers before older cows is recommended, but in some cases, infected heifers are the main source of infection.[85] Complete segregation of infected cows from uninfected cows is impossible to achieve, even if using culture results or SCC as criteria. However, segregation can have beneficial effects, particularly in herds with *S. aureus* mastitis.[86,87]

In open herds, incoming animals can introduce contagious mastitis pathogens. Purchasing cows from known sources, where historical mastitis information (bulk tank culture results, BTSCC, individual cow SCC) is available, can reduce this risk. Culturing all quarters of all new cows is the best way to screen for contagious mastitis, but this is costly, especially if *Mycoplasma* testing is performed. Negative culture results must be interpreted in conjunction with SCC or CMT values because infections (especially *S. aureus*) can be missed on a single milk culture.

36.4.2 Environmental Mastitis

With environmental mastitis, the predominant reservoir is the environment. Transmission occurs when teats become contaminated with environmental pathogens between milkings or at milking time. Common sources of infection are fecal material, bedding, soil, and contaminated water. Once environmental pathogens have been deposited on the teat skin, the gland is predisposed to infection, particularly when defense mechanisms are compromised. Environmental pathogens can also be transported into the teat canal or cistern if the teat end is not sufficiently disinfected before infusing antibiotics, or when a contaminated infusion preparation or cannula is used. The predominant environmental mastitis pathogens are coliform bacteria and streptococci other than *S. agalactiae* (environmental streptococci). However, many other environmental organisms are capable of causing mastitis.

36.4.2.1 HOUSING AND HUSBANDRY RISK FACTORS

The five-point mastitis control program does not effectively control environmental mastitis. Control requires reducing exposure of teats to environmental pathogens. This is accomplished by frequently removing manure from lots, alleyways, and other cow holding areas; rotating pastures and providing sufficient shelter to minimize congregation of pastured cows; limiting access to wet, muddy areas; avoiding overstocking; using appropriately designed stalls; and managing bedding to control pathogen load. Stall design and bedding comfort impact a cow's willingness to use the stall. If poor stall design or insufficient bedding results in discomfort or injury to the cow or hinders her ability to lunge forward and rise, the cow will choose to rest in a less sanitary location. The same is true for a barn with poor ventilation. Poor sizing of stalls may allow manure and urine to accumulate in the bedding, rather than being deposited in the alley.

Sand is the favored bedding material because it is inorganic and comfortable, as long as the beds are well maintained. However, not all manure handling systems can handle sand, and it is not always readily available. Many organic materials, such as straw, sawdust, newspaper, recycled manure, or rice hulls, are acceptable if stored properly and replaced frequently. However, bacterial concentrations greater than 10^6/g can develop in less than 24 hours, especially if the bedding is contaminated with manure. Mattresses or

rubber mats can be used but must be replaced or repaired when worn and topped with organic bedding material as needed to ensure comfort.

36.4.2.2 UDDER HYGIENE PRACTICES

Because it is impossible to eliminate teat exposure to environmental pathogens, cleaning teats in the milking parlor is an important component of environmental mastitis control. Premilking germicidal teat disinfection *(predipping)* is the preferred method in the United States. To be effective, the teats must be wiped of gross organic material, and the germicide must contact the skin for approximately 30 seconds before being removed with a towel. All surfaces of the teat, including the teat end, must contact the dip and be thoroughly cleaned. Massaging the teat helps to distribute the dip, clean the skin, and stimulate milk ejection.

An alternative to predipping is washing the teats with water containing a sanitizing solution. Only the teats should be washed, keeping the udder dry to avoid droplets of water from pooling on the teat cups and contaminating the teats.

With either method, the teats must be clean and dry when the milking cluster is attached. Dry wiping of the teats without washing or predipping is inferior for removing bacteria. Clipping or flaming of udder hair reduces the amount of fecal material and bedding that adhere to the udder and facilitates cleaning of the teats; however, the effect on mastitis incidence has not been adequately studied. Tail docking has proved ineffective at reducing mastitis risk.[88,89]

Postmilking teat disinfection does not provide a sufficient duration of germicidal activity to protect teats effectively against infection with environmental pathogens between milkings.

36.4.2.3 MANAGEMENT OF DRY COWS

Environmental mastitis can be acquired during the dry period as well as during lactation. In fact, infection risk is increased in the early and late phases of the dry period, when secretions accumulate in the gland and defense mechanisms are compromised. Many of these infections do not manifest as clinical mastitis until early lactation. Housing conditions and management practices for dry and parturient cows should minimize exposure of the teats to pathogens. Individual calving pens that are cleaned between cows are preferable to group pens that are cleaned less frequently.

Antibiotic therapy at dry-off can reduce environmental streptococcal mastitis by resolving existing infections and preventing new infections in the early dry period.[12,84] However, by the late dry period, antibiotic concentrations are too low to protect against environmental streptococcal infection. Antibiotic therapy at dry-off is generally ineffective for resolving or preventing infections caused by coliform bacteria or other environmental pathogens. An alternative or (preferably) adjunct to antibiotic therapy is use of an external or internal teat sealant to provide a physical barrier against pathogen invasion. External teat sealants are applied at dry-off or in the late dry period, but must be monitored for peeling and reapplied as needed.[90] Internal teat sealant is infused into the teat at dry-off and remains in the teat until physically removed after calving.[91]

36.5 PATHOGEN DETECTION

To address herd mastitis problems or develop appropriate treatment protocols for clinical mastitis, it is necessary to identify the responsible pathogen(s). Microbiologic culture of milk is the current “gold standard” method of

pathogen identification. Milk from individual mammary glands (quarter samples) can be cultured, as can composite milk from all four mammary glands (composite samples), pooled milk from particular groups of cows (pooled or string samples), or bulk tank milk; the choice of sample depends on the question being investigated.

For milk culture results to be accurate, milk samples must be collected aseptically, stored and handled properly, and plated on appropriate media. The volume of milk cultured, laboratory methods used, experience of the interpreter, and criteria for defining intramammary infection all influence results.

36.5.1 Sample Selection

36.5.1.1 QUARTER VS. COMPOSITE MILK SAMPLING

Quarter samples are appropriate for identifying the cause of clinical mastitis in affected glands. Although it is best to collect the milk before administering antibiotics, the presence of antibiotics in milk does not preclude culturing. In one study, mastitis pathogens were isolated from 92% of milk samples collected 12 to 24 hours after antibiotic treatment.[92] Quarter samples can also be used to determine if infection has resolved after treatment.

Quarter samples are more sensitive for detecting *S. aureus* infection than are composite samples, although the sensitivity of composite samples increases with the number of infected glands per cow.[93,94] Sampling the cow on more than one occasion (quarter or composite samples) increases the likelihood of detecting glands that intermittently shed *S. aureus*.[95] Quarter samples are also preferable to composite samples for detecting *Mycoplasma* mastitis; a recent study showed that up to 40% of glands infected with *Mycoplasma* species shed less than 100 colony-forming units (CFU)/mL of milk.[96] In contrast, single composite milk samples are acceptable for detecting cows infected with *S. agalactiae* because bacterial shedding is heavier and more consistent.[97]

When screening cows for subclinical intramammary infections, it is less time-consuming and costly to collect composite samples than quarter samples. However, pathogens from infected glands are diluted by milk from uninfected glands, which reduces sensitivity and can lead to false-negative culture results. Also, there is more risk of a composite sample becoming contaminated during the collection process. An alternative to composite sampling is to select quarters for culture using the CMT. The specificity of the CMT is high, especially if using a high threshold (score ≥2), meaning that most CMT-positive samples will yield growth. However, sensitivity is likely to be less than 50% regardless of the threshold, meaning that many infected glands will be missed.[98]

Some producers routinely culture composite milk from cows at calving or select quarters for culture using the CMT. Such culturing provides a general assessment of udder health, which reflects the adequacy of management practices for dry cows and heifers. However, culturing for the purpose of selecting animals or quarters for antibiotic treatment is unlikely to be accurate or economical. The sensitivity and specificity of the CMT for detecting infection in the first week after calving are moderate at best,[60,66] and antibiotic treatment is likely to be beneficial only for streptococcal infections.[99] The costs associated with CMT screening, culturing, antibiotic therapy, and milk discard will probably outweigh the benefits, unless the prevalence of streptococcal mastitis is high.

1118 1119

36.5.1.2 BULK TANK MILK SAMPLING

Bulk tank milk is cultured to assess the udder health status of a herd, troubleshoot milk quality problems, or evaluate the adequacy of premilking hygiene practices. In the United States, processing plants routinely test bulk tank milk for aerobic bacteria (standard plate count, SPC) and SCC (BTSCC) and may test for psychotrophic, thermoduric, or coliform bacteria. Results of these cultures help to distinguish milk quality problems caused by mastitis from those caused by poor premilking hygiene, contaminated water, improper cooling of milk in the bulk tank, or unsanitary milking equipment.[100] However, processing plants do not routinely speciate aerobic bacteria or test for *Mycoplasma* species. More comprehensive milk cultures are useful for determining the contagious mastitis status of a herd.

Detection of *S. agalactiae, S. aureus,* pathogenic *Mycoplasma* species, or *C. bovis* in bulk tank milk implies there are infected cows in the herd. However, concentrations of these pathogens in bulk tank milk are not indicative of the number of infected cows or glands.[101] The BTSCC should be high if infections are prevalent, but BTSCC cannot be used to predict the prevalence. Failure to detect contagious mastitis pathogens in bulk tank milk, especially *S. aureus,* which is shed intermittently and in relatively low concentrations, does not mean that a herd is free of intramammary infection.[101,102] Also, milk from cows with clinical mastitis is diverted from the bulk tank, which prevents the causative pathogens from being detected. To improve the sensitivity of bulk tank or pooled-milk cultures, at least four samples should be cultured on different days. Culturing of milk filters is less sensitive for detecting contagious pathogens than is culturing of bulk tank milk.[102]

Detection of environmental streptococci, coliform bacteria, or coagulase-negative *Staphylococcus* species in bulk tank milk does not imply a mastitis problem. Although these pathogens may be originating from infected mammary glands, they can also come from teats that are not effectively cleaned and dried before milking. Contaminated teats predispose to environmental mastitis, so when high concentrations of environmental bacteria are found in bulk tank milk, it is important to assess premilking hygiene practices and farm conditions that impact teat cleanliness.

36.5.1.3 POOLED MILK SAMPLING

Culturing pooled milk from a subset of cows, rather than the entire herd, allows screening of specific groups or strings of cows for the presence of contagious mastitis. To accomplish this, the bulk tank is sampled before and after milking the cows in question, and results are compared. Alternatively, aseptically collected milk samples from individual cows may be pooled.

36.5.2 Sample Collection, Storage, and Handling

36.5.2.1 SAMPLING COWS

Teat ends must be thoroughly disinfected before collecting milk, to avoid introducing skin or environmental organisms into the sample. Typical preparation practices include dry-wiping the udder to remove loose debris that could fall into the tube, stripping a few streams of milk from the teat to remove organisms in the teat canal, and scrubbing the teat end with alcohol-soaked cotton swabs or gauze pads; scrubbing should continue until the swabs or pads appear clean. Wearing gloves and dipping the teats in a germicidal solution before

scrubbing the teat ends further reduce contamination risk. The risk of a contaminated sample is lower when milk is collected after milking, but premilking (foremilk) samples are more sensitive for detecting many pathogens.[103]

Milk should be collected in sterile tubes or sterile sealable bags. The tube or bag must not touch the teat. Milk should be directed into the tube or bag at an angle, to avoid placing the tube or bag directly under the teat, where it could become contaminated with falling debris from the udder. The cap of the tube must remain sterile and space left at the top of the tube or bag to accommodate expansion during freezing. When sampling multiple teats, the far teats should be scrubbed before the near teats and the near teats sampled first, to avoid contamination by the sampler's arm or hand. Failure to use aseptic technique can produce culture results that are not interpretable or are falsely interpreted. Samples must be refrigerated at 4° C, held on ice, or frozen until cultured.

36.5.2.2 SAMPLING BULK TANK

Milk should be aseptically collected from the top of the bulk tank using a sanitized dipper. Alternatively, a sterile uterine infusion rod attached to a 60-mL syringe works well. The sample should be collected shortly after the herd is milked and after agitating the milk for 5 to 10 minutes.[104] Bulk tank milk should be placed on ice or refrigerated and cultured within 36 hours of collection; freezing is required if longer storage is necessary.

36.5.3 Selection of Media

The media used for quarter or composite milk samples depends on the pathogen(s) of concern. Blood agar (5%), the most common medium, allows growth of most aerobic mastitis-causing pathogens. Addition of esculin or staphylococcal beta-toxin facilitates identification of streptococci. Clinical mastitis samples are often plated on MacConkey medium, which selects for gram-negative bacteria and facilitates diagnosis of coliform mastitis. Biplates are available that contain both blood agar with esculin and MacConkey agar. A variety of selective media for streptococci and staphylococci are also available. Triplates and quadplates incorporate streptococcal and staphylococcal media along with blood and MacConkey agar. The use of biplates, triplates, or quadplates facilitates pathogen identification by farm personnel.[105] *Mycoplasma* spp will not grow on blood agar and requires special media and enhanced—carbon dioxide (CO_2) incubation conditions. Therefore, if milk samples are to be tested for *Mycoplasma* spp, it is important to notify the laboratory.

Bulk tank milk samples should be plated on a variety of media to facilitate detection and quantification of streptococci, staphylococci, coliform bacteria, and (when of concern) *Mycoplasma* species.

36.5.4 Inoculum Size and Laboratory Methods

The amount of milk plated determines the lower limit of pathogen detection. For example, a 0.01-mL (10-µL) inoculum allows detection of approximately 100 CFU/mL of milk, whereas a 0.1-mL (100-µL) inoculum detects concentrations as low as 10 CFU/mL. With the traditional method of milk culturing, a swab or 0.01-mL loop is used to plate the sample onto one quadrant of a plate; this allows four samples to be cultured per plate. Larger (0.05- or 0.10-mL) inocula increase recovery rates for pathogens shed in low concentrations, such as *E. coli* or *S. aureus*. Other ways to increase recovery are preculture centrifugation,[106] incubation,[94,107,108] or freezing[108] of the milk, or a combination of these methods. The optimal method is pathogen dependent.

Augmented methods are most useful for detecting subclinical *S. aureus* infections and reducing false-negative results for clinical mastitis samples. Some reports suggest that freezing negatively impacts the isolation of *E. coli* from milk,[109,110] but this is not the case in all studies.[111]

1119

1120

A selective culture system marketed for isolation and enumeration of specific pathogens from food products (Petrifilm plates, 3M, Minneapolis) was more sensitive (88%) than traditional milk culture (66%) for detecting *S. aureus* in milk and provided results within 24 hours. However, this test requires subjective interpretation of color changes, which leads to false-positive results if the person reading the films is inexperienced.[94]

The inoculum volume used for bulk tank milk varies among laboratories. Larger inocula (e.g., 0.1 or 0.2 mL) enhance detection of pathogens that are present in low concentrations. Preculture incubation (95° F for 18 hours) of bulk tank milk dramatically increased detection of *S. aureus* in one study.[112]

36.5.5 Interpretation of Culture Results

Pathogen identification procedures are described in detail in the *Laboratory Handbook on Bovine Mastitis* published by the NMC.[113] In most cases, it is not essential to identify mastitis pathogens to the species or strain level. For routine diagnosis and treatment purposes, it is sufficient to categorize isolates as *S. agalactiae*, other *Streptococcus* or *Enterococcus* species, coagulase-positive *Staphylococcus* species, coagulase-negative *Staphylococcus* species, coliform bacteria, *Corynebacterium* species, *Arcanobacterium (Actinomyces) pyogenes, Bacillus* species, yeast, or "other." Most isolates can be tentatively categorized on the basis of colony morphology, hemolysis pattern, Gram stain results, and catalase testing. Use of blood agar that contains esculin and staphylococcal beta-toxin allows differentiation of *S. agalactiae* from other streptococci and enterococci; alternatively, separate CAMP and esculin tests can be performed. Coagulase testing distinguishes coagulase-positive staphylococci (assumed to be *S. aureus*) from less pathogenic coagulase-negative species. As previously mentioned, use of biplates, triplates, or quadplates can facilitate pathogen categorization.[105] When speciation or further confirmation is desired, a variety of biochemical and nonbiochemical testing methods can be used. *Mycoplasma* isolates must be speciated to distinguish potential mastitis pathogens from incidental, nonpathogenic species.

Deoxyribonucleic acid (DNA) fingerprinting, phage typing, ribotyping, pulse-field gel electrophoresis, multilocus gene sequencing, and other molecular methods of pathogen typing can provide valuable information about the source and spread of infection in herds with mastitis problems. For example, ribotyping identified a cat with chronic sinusitis as the probable source of a herd outbreak of *Streptococcus canis* mastitis.[114] DNA fingerprinting demonstrated that many cows with recurrent episodes of clinical *E. coli* mastitis had chronic infections,[115] challenging the assumption that *E. coli* infections resolve spontaneously shortly after the onset of disease. Typing techniques allow bacterial isolates from potential environmental reservoirs to be compared with those causing high SCC or clinical mastitis[116] and can help identify the source of bacteria in bulk tank milk.[117] As molecular technologies become more affordable, their use in mastitis investigations is likely to increase.

36.5.6 Definition of Infection

No universally accepted criteria exist for defining intramammary infection. Researchers require growth of the same pathogen in at least two of three consecutive milk samples, growth of the same pathogen in duplicate milk samples collected simultaneously, or growth of a pathogen in conjunction with indirect evidence of infection (high SCC, positive CMT, or clinical signs of mastitis). In practice, it is too costly to collect consecutive or

duplicate milk samples. Therefore, diagnosis is usually made on the basis of a single milk culture result; fortunately, most cultures are from cows with clinical mastitis or high SCC, providing indirect evidence of infection.

Confidence in culture results is greatest when a single pathogen is isolated in pure culture. However, co-infections do occur. When three or more colony types are isolated from a given sample, the sample is considered contaminated. However, even in a contaminated sample, growth of a single colony of *S. agalactiae* or *S. aureus* is considered significant.

36.5.7 Alternative Methods of Pathogen Detection

Clinical mastitis episodes caused by gram-positive bacteria are usually treated with antibiotics, whereas antibiotics are not required for many coliform mastitis episodes (see section on clinical mastitis treatment). A variety of nonculture schemes using historical data (e.g., parity, stage of lactation, season of year) and clinical signs (e.g., rectal temperature, rumen contraction rate, appearance of milk) have been developed to distinguish coliform mastitis from mastitis caused by gram-positive bacteria.[118–121] Unfortunately, none of these schemes is sufficiently accurate to be used as a basis for antibiotic treatment decisions. Although veterinary practitioners often believe they can recognize coliform mastitis, one study showed that practitioners correctly identified only 23 of 36 (63%) coliform mastitis episodes and misidentified 32 of 82 (39%) noncoliform episodes.[122] An artificial neural network and a model using inductive inference were only able to accurately classify bacterial pathogens about 60% of the time.[123]

Cow-side tests that detect LPS in milk have been used to identify gram-negative mastitis episodes.[124] However, these tests are not available in the United States. A method that distinguishes gram-positive and gram-negative bacteria in milk by adding a reagent, incubating the mixture in hot tap water for 2 minutes, filtering the mixture through a membrane, and staining the membrane has been described.[125] Unfortunately, the limit of detection of that method was 10^6 CFU/mL or greater for *E. coli* and *S. aureus,* which is too high for many mastitis episodes.

Cows with gram-negative clinical mastitis are more likely to be neutropenic and monocytopenic and to have higher blood hemoglobin concentration than cows with gram-positive clinical mastitis. The sensitivity of the combination of these hematologic parameters for detecting gram-negative mastitis was 93%, and specificity 89%, in one study.[126] If a laboratory is not available or a complete blood count (CBC) is considered too costly, the percentage of segmented neutrophils and monocytes on a blood smear can be used; sensitivity and specificity of differential cell counts were 87% and 71%, respectively.

Polymerase chain reaction (PCR) technology has allowed development of a number of PCR tests for mastitis pathogens. With PCR, pathogens are detected and definitively identified more rapidly than by milk culture. Unfortunately, because PCR primers are specific for particular pathogens, PCR cannot be used to test milk for a wide range of mastitis-causing pathogens. Multiplex PCR overcomes this limitation to some extent. For example, a recently developed multiplex real-time PCR method for simultaneous detection of *S. aureus, S. agalactiae*, and *Streptococcus uberis* correctly identified 96% of quarter milk samples.[127] PCR is also used for detecting *Mycoplasma* mastitis because culture results can take more than a week.[128] Now that techniques have been developed to overcome the inhibiting effects of milk on PCR, PCR testing will likely become more widespread.

36.6 SPECIFIC MASTITIS INFECTIONS

36.6.1 *Streptococcus agalactiae* Mastitis

Herds that conscientiously use the control measures described earlier in the five-point plan can eliminate or greatly reduce *S. agalactiae* mastitis within a few years. However, *S. agalactiae* spreads rapidly when effective control measures are not in place and can cause substantial economic loss. Most episodes of *S. agalactiae* mastitis are subclinical and last for months or years if not treated. Subclinical infection may be interspersed with bouts of mild clinical mastitis, but cows do not become systemically ill.

Streptococcus agalactiae adheres to epithelial cells in the mammary gland and localizes primarily in the ducts. Milk production declines when ducts become blocked with cells and debris and the associated alveoli involute. Early treatment can restore milk production because permanent damage to the gland is minimal. However, tissue damage, fibrosis, and a permanent decrease in milk production can occur if infection becomes chronic. *S. agalactiae*–infected glands tend to shed high concentrations of bacteria and SCC in milk. Even a small number of infected cows can increase the SCC or SPC of bulk tank milk and result in milk quality penalties.[129–131]

Streptococcus agalactiae mastitis should be suspected in herds that have a high or increasing BTSCC or a large or increasing proportion of cows with persistently elevated SCC. Growth of esculin-negative, CAMP-positive streptococci in milk from the bulk tank or from individual cows confirms *S. agalactiae* infection. Composite milk from all cows in the herd must be cultured to determine the prevalence of infection and identify positive cows. PCR is a promising alternative to milk culture.[127,131–133]

36.6.1.1 Treatment

S. agalactiae is highly susceptible to penicillin and other antibiotics marketed for intramammary infusion in the United States. Bacteriologic cure rate typically exceeds 90% after a single course of therapy during lactation[134–136] or at dry-off.[137] Therefore, in herds with prevalent *S. agalactiae* mastitis and high economic loss, it is acceptable to mass-treat (“blitz-treat”). This is accomplished by treating all lactating cows or (preferably) culturing milk from all lactating cows and treating those with *S. agalactiae* infection; all four quarters of each cow are treated. Cows that are close to the end of lactation can be dried off and dry-treated. A small proportion of cases will fail to cure or will be missed on milk culture, so it is essential to institute effective control measures in conjunction with blitz treatment. Although the initial cost of blitz treatment is high, the benefit/cost ratio usually exceeds 2:1 because of an increase in milk production and decline in BTSCC.[135,138,139]

Failure to disinfect teat ends adequately before blitz-treating cows, or use of contaminated antibiotic solutions or infusion equipment rather than commercially available antibiotic tubes, can result in financially devastating outbreaks of environmental mastitis.[140–142] Therefore, veterinarians or other personnel who are trained in aseptic technique should perform the infusions, using commercially available tubes. Systemic antibiotics are not necessary or recommended for treatment of *S. agalactiae* mastitis.[136]

36.6.1.2 Control

Control measures for *S. agalactiae* mastitis are described in the section on contagious mastitis. Postmilking germicidal teat dipping and dry-cow antibiotic therapy are the most important measures. Introduction of infected cows to a herd can lead to rapid spread of *S. agalactiae* mastitis if control measures are not meticulously carried out. Purchasing animals from an *S. agalactiae*–free herd or culturing milk before putting cows in the milking herd can reduce this risk. Vaccines are not available or necessary for control of *S. agalactiae* mastitis.

36.6.2 *Staphylococcus aureus* Mastitis

Most dairy herds have cows with *S. aureus* mastitis, but the prevalence and economic impact vary. As for *S. agalactiae*, most *S. aureus* intramammary infections are chronic and subclinical, with periodic bouts of clinical mastitis. However, clinical *S. aureus* mastitis ranges in severity from mild to gangrenous. Herds with a high prevalence of *S. aureus* mastitis cannot be distinguished from those with a high prevalence of *S. agalactiae* mastitis without culturing milk; in some cases, both pathogens are prevalent. Herds with *S. aureus* or *S. agalactiae* mastitis tend to have a high or increasing BTSCC and a large or increasing proportion of cows with persistently elevated CMSCC; however, *S. agalactiae* mastitis tends to cause higher SCC and a higher bulk tank bacteria count.

Staphylococcus aureus mastitis is presumptively diagnosed by isolating coagulase-positive staphylococci from bulk tank milk or infected glands, particularly if colonies are surrounded by a double zone of hemolysis (complete hemolysis surrounded by incomplete hemolysis). Because certain *S. aureus* strains are coagulase negative[143] and other *Staphylococcus* species (e.g., *S. hyicus*) can be catalase positive,[144] definitive identification requires additional diagnostic testing. Herds typically have a predominant strain of *S. aureus,* with additional strains appearing sporadically.[145] Strains of *S. aureus* differ in contagiousness, virulence, and antibiotic susceptibility, leading to variable responses to treatment and control measures among herds and among cows.[146–148] In some cases, multiple strains of *S. aureus* co-inhabit a gland or cow.[149] Resolution of infection with one strain can be followed by infection with another strain.[150]

Staphylococcus aureus adheres to and invades mammary epithelial cells and interstitial tissue.[151–153] It also resists phagocytosis by neutrophils. Antiphagocytic mechanisms include a capsule that inhibits opsonization and a surface protein (protein A) that binds the Fc portion of host Ig. Leukotoxin production enables some *S. aureus* strains to kill phagocytes.[154] Other mechanisms allow *S. aureus* to survive within leukocytes and epithelial cells and induce apoptosis.[153,155,156] *S. aureus* strains produce a variety of enzymes and exotoxins that damage mammary cells and result in fibrosis and abscess formation.[157] Some strains produce β-lactamase, conveying resistance to antibiotics such as penicillin and amoxicillin. Others convert to L-form or small colony variants, which can persist with antibiotic therapy.[158–160] Certain *S. aureus* strains form adherent colonies surrounded by a biofilm, making them inaccessible to phagocytes and antibiotics[161,162]; biofilm-associated proteins are associated with persistent *S. aureus* mastitis.[161] For these reasons, *S. aureus* intramammary infections seldom resolve spontaneously and are difficult to treat with antibiotics.

36.6.2.1

Treatment

A number of cow factors influence the response of *S. aureus* to antibiotic treatment during lactation or at dry-off.[163] These include parity, stage of lactation, SCC, and quarter.[66,164–166] Older cows (parity >2), cows in early to midlactation, quarters with SCC greater than 1×10^6/mL, and rear quarters have a higher risk of treatment failure compared with young cows, cows in late lactation, quarters with low SCC, and front quarters. Duration of infection and bacterial concentration in milk are also negatively correlated with cure rate.[66,164] Infection in multiple quarters reduces cure rate at the cow level.[164] Because pathogen and cow factors can greatly impact treatment response, blitz treatment should never be attempted, even in herds with a high prevalence of infection. Rather, treatment decisions should be made on a case-by-case basis, considering the cow's history, value, and likelihood of cure.

1121

1122

Intramammary antibiotics are the mainstay of *S. aureus* mastitis treatment. Beta-lactamase—resistant antibiotics, such as cephapirin, ceftiofur, or cloxacillin, should be used unless isolates are tested for β-lactamase production.[167] Even when β-lactamase—producing *S. aureus* strains are treated with β-lactamase—resistant antibiotics, the cure rate tends to be lower than for β-lactamase—sensitive strains[148]; therefore, β-lactamase testing can be prognostic. Most intramammary antibiotics marketed in the United States are labeled for two or three doses 12 or 24 hours apart. The bacteriologic cure rate associated with a typical 2- or 3-day treatment regimen is very low. Increasing the duration of treatment increases the time above the minimum inhibitory antibiotic concentration (MIC) for the pathogen, which should increase the likelihood of cure. Indeed, a 4-, 5-, or 8-day treatment regimen was superior to a 2-day regimen or no treatment in several studies.[166,168,169] However, even with extended therapy, the cure rate can be less than 50%.[170] Infusing antibiotics per label directions on three occasions, with a withholding period after each treatment period ("3-peat therapy"), avoids extralabel drug use, but cure rates vary widely (14% to 50%) among studies.[171]

Duration of intramammary antibiotic treatment is irrelevant if the antibiotic cannot reach bacteria that are sequestered within cells or abscesses. Inflammation and swelling in *S. aureus*–infected glands can also reduce the distribution of intramammary antibiotics.[172] Concurrent use of systemic antibiotics that achieve effective concentrations in mammary tissue and milk should augment intramammary antibiotic therapy, but few well-designed studies have addressed this question. In one study the cure rate of *S. aureus* mastitis was twofold higher (51% vs. 25%) when six intramammary infusions of amoxicillin were accompanied by three intramuscular (IM) injections of procaine penicillin.[159] A combination of intramammary and systemic antibiotics also appears to be superior to systemic antibiotics alone.[148]

The variability in cure rates observed among herds, regardless of antibiotic treatment regimen, likely reflects cow selection and the strains of *S. aureus* in the herd.[173] Milk from treated cows should be cultured at least twice after the end of the antibiotic-withholding period before cure is presumed; increasing the number of cultures will detect more unresolved infections.[165,174]

36.6.2.2

Control

The five-point mastitis control plan (see contagious mastitis) effectively reduces the incidence and prevalence of *S. aureus* mastitis but does not eradicate it. Some strains persist in the face of excellent milking hygiene practices, necessitating strict segregation, culling, and drying off of infected cows to control an

outbreak.[87] The five-point plan will not necessarily control sporadic infections with nonpredominant strains.[147] Those strains may be harbored outside the mammary gland and require different control measures. New *S. aureus* infections can develop during the dry period, when glands are not being milked,[150] attesting to alternative reservoirs of infection, such as the environment or skin.

Herds that purchase replacement heifers have a higher prevalence of *S. aureus* mastitis and more *S. aureus* strains than do closed herds, illustrating the importance of biosecurity in mastitis control.[145] Because the predominant strains of *S. aureus* differ among herds, even those close to one another,[175] measures that effectively control *S. aureus* mastitis in one herd may fail in other herds in the same geographic area. Cows with resistant *S. aureus* mastitis or a low likelihood of cure should be culled as soon as economically feasible, or segregated and milked last. Alternatives are simply to stop milking the infected gland or to induce cessation of lactation by infusing a disinfectant solution (see treatment of clinical mastitis).

Highly effective vaccines for *S. aureus* mastitis are not available. Commercially available, multistrain bacterins provide variable protection against acute and chronic infection,[176–179] and protection is typically of short duration. Vaccination may enhance the spontaneous cure rate,[176] reduce SCC,[176,179] or reduce the severity or duration of clinical mastitis,[178] but again, results vary. Efficacy likely depends on the relatedness of the *S. aureus* strains in the bacterin to strains present in the herd. Herd-specific autogenous bacterins have generally failed to provide protection,[180,181] possibly because of the components of the bacterin or dosing regimen. In general, *S. aureus* bacterins appear to be more protective in heifers than in cows.

Recently, *S. aureus* vaccines have been used in combination with extended intramammary antibiotic therapy in an attempt to increase bacteriologic cure rate.[171,182] Infected cows are vaccinated before and shortly after antibiotic treatment. Although experimental vaccines appeared promising, use of a commercially available bacterin in conjunction with extended pirlimycin therapy did not enhance the efficacy of pirlimycin therapy[171] and cured less than 50% of infections.[182] Vaccination strategies being investigated include delivery of *S. aureus* virulence-associated antigens in plasmid expression vectors (DNA vaccination),[183] recombinant viral vectors,[183] or microspheres.[184] Better vaccines will likely be available in the future as researchers identify appropriate antigen combinations, adjuvants, and delivery mechanisms.

36.6.3 *Mycoplasma* Mastitis

Mycoplasma species are found in a variety of extramammary body sites of cattle, such as the respiratory and urogenital tracts. Colonized cattle may be asymptomatic or may develop bronchopneumonia, otitis, polyarthritis, or mastitis. In dairy herds with *Mycoplasma* mastitis, otitis media-interna, respiratory disease, or swollen joints may be seen in calves, especially if unpasteurized milk is fed.[185] Cows may or may not exhibit clinical signs other than mastitis. Most *Mycoplasma* intramammary infections are subclinical and chronic, as with *S. agalactiae* and *S. aureus*. However, when clinical mastitis occurs, it often affects multiple glands simultaneously or in succession and fails to respond to conventional antibiotic therapy. Although the milk from cows with clinical *Mycoplasma* mastitis is visibly abnormal, the cows are usually systemically healthy.

The pathogenesis of *Mycoplasma* mastitis is not fully understood. Asymptomatic carrier animals may infect herdmates by shedding the organisms in nasal or vaginal secretions, feces, or milk. Purchased animals are often blamed for introducing *Mycoplasma* mastitis, but outbreaks can occur even in closed herds. Cow-to-cow transmission of intramammary infection is believed to occur through milk-contaminated fomites at milking

time, as with other contagious mastitis pathogens. However, it appears that *Mycoplasma* species can be transmitted from other body sites to the mammary gland, or vice versa, via the bloodstream or lymphatics. For example, experimental intramammary inoculation of *Mycoplasma* species into a single mammary gland was followed by detection of phenotypically identical *Mycoplasma* species in extramammary body sites, blood, and noninoculated mammary glands,[186,187] even when gland-to-gland transmission was prevented by a special milking device.[187] Recently, Biddle et al.[188] found that isolates of *Mycoplasma* species from the milk, mammary gland parenchyma, and supramammary lymph nodes of infected cows all had the same pulse-field gel electrophoresis pattern, and that all cows had at least one extramammary isolate with the same pattern. These findings suggest that cows with *Mycoplasma* mastitis frequently have disseminated infections, and that internal transmission may occur.

Results of bulk tank surveys suggest that less than 10% of U.S. dairy herds have cows with *Mycoplasma* mastitis; however, the economic impact in infected herds can be substantial. Many species of *Mycoplasma* can infect the mammary gland and cause mastitis, but *M. bovis* is isolated most frequently. *Mycoplasma* infection will be missed when milk is cultured unless appropriate media and incubation conditions are used. Freezing of samples reduces the concentration of viable organisms, whereas broth enrichment before culturing can enhance detection of *Mycoplasma* species.[189] Colonies usually take 7 to 10 days to appear, and isolates must be speciated to differentiate pathogenic from nonpathogenic *Mycoplasma* strains. Because of the time required for culture and secondary speciation, PCR-based diagnostic methods have been developed. Recent PCR-based methods have acceptable limits of detection (<100 CFU/mL) and use primers that differentiate among several *Mycoplasma* species.[190] PCR-based methods likely will increasingly replace culture for detection of *Mycoplasma* mastitis.

When pathogenic *Mycoplasma* organisms are isolated from the bulk tank or milk from an individual cow, the herd probably contains more than one infected animal. Pooled milk can be cultured after milking each string of cows to help identify infected groups for further testing. Cows with clinical mastitis and those with high SCC are good candidates for testing but may not include all infected individuals.

36.6.3.1

Treatment and Control

Antibiotic treatment of *Mycoplasma* mastitis is unrewarding, at least with antibiotics that can be used in lactating cows in the United States. Although some intramammary infections may resolve spontaneously, infected cows should be considered permanently infected. Even if repeated culturing of milk from an individual quarter yields negative results, infection might persist in an extramammary site and spread to the mammary gland later. For this reason, some dairy producers cull all cows diagnosed with *Mycoplasma* mastitis. However, even aggressive diagnosis and culling programs may not prevent periodic *Mycoplasma* mastitis incidents if infections persist asymptomatically in extramammary sites. A more economical alternative to aggressive culling is to house and milk infected cows separately, culling only when indicated (e.g., persistent or recurrent clinical mastitis, low production); once a cow enters the *Mycoplasma* string, she should remain there until culled. In one study, *Mycoplasma* species were isolated from bulk tank milk for less than 1 month in 70% of herds, suggesting that producers rapidly identified and managed cows before prevalence could escalate.[191]

Although *M. bovis* bacterins are available in the United States, minimal data have been published to assess their efficacy. Vaccination against *M. bovis* is hindered because of variable expression of a diverse and ever-changing set of genes encoding surface lipoproteins (Vsps).[192]

Mycoplasma species are susceptible to germicides often found in teat dips.[193] Effective premilking and postmilking teat dipping and other measures used to prevent the spread of contagious pathogens in the milking parlor help limit *Mycoplasma* mastitis transmission. Dry-cow antibiotic therapy, however, does not reduce the prevalence of infected mammary glands. Pasteurization of waste milk reduces the risk of *Mycoplasma* transmission to milk-fed calves.[185]

36.6.4 *Corynebacterium bovis* Mastitis

Although highly contagious, *C. bovis* is considered a minor mastitis pathogen because it typically inhabits the teat canal, induces a lesser increase in SCC than other contagious mastitis pathogens, causes subclinical infection, and has little impact on milk yield.[194] *C. bovis* can cause clinical mastitis,[195,196] but the episodes are usually milder than those caused by other gram-positive bacteria or coliform bacteria.[196] As with *S. aureus*, there is often a predominant strain of *C. bovis* in a herd.[197]

Corynebacterium bovis mastitis can be controlled by measures that control other contagious mastitis pathogens.[198] A high prevalence of *C. bovis* mastitis is often attributable to poor teat-dipping practices.[195,199]

There is some evidence that *C. bovis* infection may protect against mastitis caused by major pathogens. For example, in a large case-control study, the odds of infection with a major pathogen were significantly reduced when a gland was infected with *C. bovis* than when a gland was uninfected (odds ratio [OR] = 0.52).[200] However, failure to control *C. bovis* means that contagious mastitis control measures are insufficient and the herd is at risk for an outbreak of *S. aureus, S. agalactiae*, or *Mycoplasma* mastitis should those pathogens be introduced.

36.6.5 Environmental Streptococcal Mastitis

Mastitis-causing *Streptococcus* species other than *S. agalactiae* are referred to as "environmental streptococci." These include *S. uberis, S. parauberis, S. dysgalactiae, S. equinus, S. saccharolyticus. S. salivarius, S. canis*, and others; enterococci, such as *Enterococcus faecalis* and *E. faecium*, and *Aerococcus viridans* are often grouped with the environmental streptococci. These catalase-negative, gram-positive cocci have reservoirs in the environment and act as opportunistic pathogens, whereas the main reservoir for *S. agalactiae* is infected mammary glands. This does not mean that environmental streptococcal mastitis cannot spread contagiously. Indeed, *S. dysgalactiae* is sometimes categorized as a contagious pathogen. Also, *S. canis* and some strains of *S. uberis* have been implicated in mastitis outbreaks that appear to involve cow-to-cow transmission.[114,201,202] Still, environmental streptococcal mastitis is relatively more prevalent and costly in herds that have achieved control of contagious mastitis. Most research on environmental streptococcal mastitis has focused on *S. uberis,* which is considered the most important of these pathogens.[203]

Environmental streptococci are shed in the feces of cattle and are ubiquitous in the environment on dairy farms. Fecal shedding probably accounts for isolation of environmental streptococci from water, soil, plant material, and flies.[116] Infected dogs and cats can carry *S. canis* in their respiratory and urogenital tracts and serve as potential sources of infection for cows.[114,201] *S. uberis* is found in the vagina of cows,[116] but genital tract secretions probably play little role in the transmission of infection compared with feces.

Bedding is considered to be a major source of environmental streptococcal exposure for cows housed in confinement. Environmental streptococci multiply in a wide range of bedding materials, particularly when the bedding is contaminated with feces and urine.[204,205] Straw, in particular, supports the growth of *S. uberis*. However, *S. uberis* mastitis also affects pastured cows and cows in lots that are not bedded. High-traffic races and areas of pastures or lots where cows congregate and defecate harbor *S. uberis* and serve as reservoirs.[116]

Approximately 50% of environmental streptococcal infections are initiated during the dry period.[206] The mammary gland is highly susceptible to environmental streptococcal infection during the early and late stages of the dry period, when mammary secretions accumulate and host defense mechanisms are compromised.[13,207–209] However, infection may develop at any stage of lactation. Infection is accompanied by a rapid influx of neutrophils into the mammary gland and a resultant increase in SCC. Based on experimental inoculation studies with *S. uberis*, the recruited neutrophils are unable to fully prevent bacterial multiplication.[210] Ineffective host response probably explains the prolonged infections and persistently high SCC seen in some cases.

Environmental streptococcal infections often remain subclinical, with the main impact being the increase in SCC. When the prevalence of environmental streptococcal mastitis is high, the increase in BTSCC may result in penalties or loss of quality premium payments.[201,211] In some cases, environmental streptococcal counts in bulk tank milk may exceed the regulatory limit of 100,000 CFU/mL.[117] Although a portion of the environmental streptococci in bulk tank milk come from contaminated teat skin, strain typing has demonstrated identical strains of *S. uberis* in bulk tank milk and infected mammary glands. This suggests that infected cows may contribute to excessively high bulk milk bacteria counts.[117]

Although most environmental streptococcal infections resolve within 30 days, about one third of infections persist for long periods, sometimes more than a lactation. Also, up to 50% of environmental streptococcal infections result in clinical mastitis.[206] Clinical mastitis causes economic loss as a result of discarded milk and treatment costs. Fortunately, most clinical mastitis episodes are of mild to moderate severity and do not result in marked milk production loss or death of the cow.

36.6.5.1

Treatment

Antibiotic treatment of clinical mastitis is an important component of environmental streptococcal mastitis control (see later). Treatment of subclinical mastitis is usually accomplished by intramammary infusion of antibiotics at dry-off. Antibiotic treatment of subclinical mastitis during lactation is controversial and usually discouraged. Milk yield may not increase after treatment of environmental streptococcal mastitis,[212] which limits potential economic benefit. However, effective treatment reduces the duration of high SCC and bacterial shedding, thus improving milk quality. Effective treatment also decreases clinical mastitis occurrence and reduces the risk of transmission to other quarters or cows. When these benefits were considered, partial budget modeling predicted a net profit from treating subclinical environmental streptococcal infections with a 3-day course of intramammary antibiotics.[213]

Alternatives to antibiotic administration for treating subclinical or mild clinical environmental streptococcal mastitis have been investigated. The most common alternatives are no treatment, administration of oxytocin at milking time, and frequent milk-out of the gland(s). Although oxytocin administration resulted in similar clinical and bacteriologic cure rates for mild clinical environmental streptococcal mastitis as did two or three treatments with intramammary antibiotics,[214] the subsequent rate of recurrence and new infections was

higher.[215] Adoption of a nonantibiotic approach to clinical environmental streptococcal mastitis was followed by a marked increase in bulk tank SCC and clinical mastitis in one herd, presumably caused by persistence and spread of infections.[211] Bacteriologic cure rate was increased and recurrence rate decreased in several studies in which intramammary antibiotics were compared with no treatment for mild clinical[216,217] or subclinical[212,216] mastitis. Similarly, intramammary antibiotics resulted in a higher cure rate for mild clinical environmental streptococcal mastitis than did oxytocin administration with or without frequent milking.[217,218] In one study, administering oxytocin in conjunction with intramammary antibiotics reduced the bacteriologic cure rate of experimentally induced *S. uberis* mastitis compared with antibiotics alone, suggesting a detrimental effect of oxytocin.[217] Oxytocin and frequent milking were ineffective at preventing clinical mastitis, even when initiated at the first sign of subclinical *S. uberis* infection.[219]

Susceptibility of environmental streptococci to antibiotics used in commercial intramammary infusion products in the United States varies among species, with *S. dysgalactiae* isolates being more susceptible than *S. uberis*, and enterococci being least susceptible.[220,221] However, in vitro susceptibility does not necessarily predict responsiveness to antibiotic therapy.[222,223] The bacteriologic cure rate associated with a two- or three-dose (on-label) regimen of intramammary antibiotics is usually lower for environmental streptococcal mastitis than for *S. agalactiae* mastitis.[213,215,224,225] Extending the duration of therapy increases the time that antibiotic concentration is above the MIC. Extended duration therapy (5 to 8 days) enhanced the bacteriologic cure rate in studies involving experimental[217,226] and natural[170,225,227] environmental streptococcal infections compared with on-label therapy. However, the economic benefit of extended (8-day) therapy for subclinical environmental streptococcal mastitis was predicted to be less than for 3-day therapy in one model.[213] As for *S. aureus* mastitis, the duration of environmental streptococcal infection and the magnitude of SCC probably influence the likelihood of successful antibiotic treatment, with chronic infections and infections with high SCC being difficult to resolve.[225]

Systemic antibiotic treatment is an alternative to intramammary antibiotic treatment. For example, IM administration of penethamate hydroiodide cured 59% of chronic *S. uberis* or *S. dysgalactiae* infections, versus 0% in untreated cows[212]; clinical mastitis incidence and CMSCC were also reduced by antibiotic treatment. However, systemic antibiotic therapy results in greater total antibiotic use than intramammary antibiotic therapy, and both routes appear to produce similar cure rates.[217] Therefore, intramammary antibiotic therapy is preferred.

36.6.5.2

Control

Control of environmental streptococcal mastitis involves reducing exposure of the teats to feces and fecal-contaminated fomites, such as bedding and soil. This can be accomplished by providing clean, dry, comfortable stalls or resting areas; feeding cows after milking to keep them standing; controlling environmental temperature and humidity; providing sufficient shelter to reduce congregation of cows; avoiding overcrowding; removing manure frequently; and preventing access to high-risk locations such as contaminated ponds. Particular attention should be paid to housing conditions for dry and periparturient cows because of their increased susceptibility. Sand is the preferred bedding material for housed cows, but sand that becomes contaminated with feces and urine can readily support pathogen multiplication.[205] Brisket boards, cow trainers, and other devices used to position cows properly in stalls can reduce contamination of the bedding. Management of bedding is critical to avoid buildup of environmental streptococci. Frequent removal and replacement of organic bedding material are essential because environmental streptococcal

1124
1125

concentrations can escalate within 24 hours under the right conditions.[204,205] Alkaline and acidifying bedding conditioners may transiently inhibit bacterial growth, but efficacy depends on the type of bedding and declines within 2 to 6 days after application.[228]

If facilities and environmental hygiene practices are appropriate, udders should be relatively clean and dry when cows enter the milking parlor. Cleanliness scoring systems have been developed to facilitate assessment of udder hygiene and monitor changes in hygiene over time.[89,229] Clipping or flaming of udder hair should reduce accumulation of bedding material and feces. However, this practice did not reduce teat skin or milk bacterial concentrations or intramammary infection risk in a herd with excellent premilking hygiene practices.[230] Tail docking, although a seemingly logical procedure for reducing fecal contamination of the udder, does not significantly improve udder cleanliness or reduce mastitis risk[88,89]; clipping of the switch is a more humane alternative to reduce manure on the tail.

Even visibly clean teats should be disinfected before milking to reduce bacteria on the skin and in the bulk tank.[231] Predipping is an effective way to accomplish this, provided gross organic matter is removed first and the germicide contacts the skin of the entire teat for a sufficient time (20 to 30 seconds) before being removed.[231–233] Failure to effectively wipe the teats to remove the dip can result in germicide residues in the bulk tank milk.[234] Washing of each teat with water containing a sanitizing solution is an alternative to predipping, provided the water is clean, excessive wetting of the udder is avoided, and the teats are thoroughly dried using clean towels.[231] Predipping and drying were more effective at preventing experimental *S. uberis* intramammary infections than washing and drying in one study.[232] Thorough cleaning and drying of the teats, with or without forestripping, provide the stimulation and time needed to elicit milk ejection, which minimizes milking time and the risk of milking-induced teat trauma.[235]

Postmilking teat disinfection may reduce environmental streptococci on the teat skin and thereby potentially prevent new infections from developing immediately after milking. However, postmilking teat disinfection does not protect cows against teat contamination or infection between milkings or during the dry period. Dry-cow antibiotic therapy is used to resolve environmental streptococcal infections that are present at dry-off and prevent new infections during the early dry period.[12,84] Unfortunately, antibiotic activity is not sufficient to prevent new infections in the late dry period.[209]

To help protect the teats from environmental streptococcal infection throughout the dry period, an internal teat sealant can be infused into all four quarters at dry-off. This inert material (bismuth subnitrate) remains in the teat cistern, providing a physical barrier against infection until removed after calving. Internal teat sealant used alone reduces new environmental streptococcal infections during the dry period compared with no treatment.[236] New infection rates are similar for quarters treated with teat sealant or antibiotics at dry-off.[237–239] However, the combination of antibiotics and teat sealant is superior for preventing new environmental streptococcal infections during the dry period and is also indicated if the prevalence of infection at dry-off is high.[91,238] External teat sealants are an alternative to internal sealants but are more cumbersome to use because teats must be monitored frequently and the sealant reapplied as needed.[90]

Because of the large number of species and strains of bacteria that cause environmental streptococcal mastitis, vaccination is not a feasible general control measure. Vaccines that specifically target *S. uberis* hold promise[203] but will not replace hygiene as the mainstay of mastitis control.

36.6.6 Coliform Mastitis

Coliform mastitis is a major cause of disease in many well-managed dairy herds, accounting for approximately 30% to 50% of clinical mastitis episodes.[240] Although *E. coli* causes most coliform mastitis episodes, *Klebsiella* species are important contributors on some farms, with *Enterobacter* species isolated less frequently. Other gram-negative mastitis-causing bacteria, such as *Serratia, Pseudomonas, Salmonella, Proteus,* and *Pasteurella,* are discussed later. Coliform mastitis can be distinguished from noncoliform mastitis by culturing milk on MacConkey agar and observing the characteristic pink colonies indicative of lactose fermentation.

As with environmental streptococci, coliform bacteria are shed in the feces and are ubiquitous on dairy farms. A wide variety of strains are capable of causing mastitis.[241] Mastitis develops after teats are exposed to feces or to contaminated bedding, water, or soil. Organic bedding materials, such as straw, wood chips, sawdust, recycled manure, pelleted corncobs, and newspaper, support the growth of coliform bacteria, particularly under warm, wet conditions.[242,243] Sawdust bedding has been implicated in outbreaks of *Klebsiella* mastitis,[244] but *Klebsiella* species can proliferate rapidly in other bedding materials as well. Intramammary infections and clinical coliform mastitis tend to increase during summer.[245] Rainfall, stocking density, frequency of manure removal, and frequency of pasture rotation can also influence the extent of exposure and risk of intramammary infection.

The majority of coliform intramammary infections develop during the early and late phases of the dry period.[208,246] These infections usually remain subclinical until after parturition. Most clinical coliform mastitis episodes that develop during early lactation are the result of infections acquired during the dry period.[208,246] Also, quarters that were infected during the dry period are at higher risk of clinical mastitis in early lactation than are quarters that were not infected.[246] In one study, *E. coli* infection during the late dry period was associated with an increased risk of culling in the next lactation.[209] Although the dry period and early lactation are times of high risk for coliform mastitis, it can develop at any time during lactation, particularly if exposure is high and cows are stressed.

The majority of clinical coliform mastitis episodes are mild, with less than 10% causing systemic illness or a marked drop in milk production.[120,247] However, coliform mastitis accounts for the majority of severe clinical mastitis episodes on most farms.[248] The outcome of clinical coliform mastitis depends on the severity, which reflects the cow's immune response (see later). Systemic signs are better than local signs or a combination of systemic and local signs for predicting coliform mastitis outcome.[249] High or subnormal rectal temperature, reduced rumen contraction rate and amplitude, marked dehydration, and marked depression are associated with increased risk of death, culling, or poor return to milk production.[76,79] Severe neutropenia[79] and high bacterial concentration in the milk[79,250] are also indicative of a poor prognosis. Cows in early lactation cows do not develop neutropenia to the extent observed in later lactation; therefore the leukon is not a good indicator of mastitis severity in early lactation cows.[126,251]

1125 1126

Once in the mammary gland, coliform bacteria multiply rapidly but do not adhere to or invade the epithelial cells.[252] Therefore, if the cow's immune response is rapid and efficient, infection will be eliminated quickly, with little long-term impact on cow health or productivity. This is what usually happens when healthy cows are experimentally inoculated with *E. coli* and when cows develop coliform mastitis in mid- to late lactation. In such cases, cows are referred to as “mild responders” or “moderate responders.” However, when influx of

neutrophils is delayed or phagocytosis or intracellular killing mechanisms of neutrophils impaired, bacterial multiplication continues, resulting in high bacterial concentrations in the milk and severe clinical disease. This happens most frequently in the periparturient period and early lactation. In such cases, cows are referred to as "severe responders," and prognosis for recovery is worse.[25,55,253,254] Responsiveness does not depend solely on stage of lactation and varies among cows. Indeed, it is believed that cow factors, rather than bacterial factors, are the predominant determinants of coliform mastitis outcome.[252]

As coliform bacteria multiply and die in the mammary gland, LPS (endotoxin) is released from the cell wall. Binding of LPS to host cells results in release of TNF-α, which is largely responsible for initiating the inflammatory cascade that causes the local and systemic signs of coliform mastitis.[255,256] Important contributors to the inflammatory response include prostaglandins,[257] IL-1, IL-6, and IL-8,[25] C5a,[258] nitric oxide,[256,259] and acute-phase reactants.[254] Although LPS concentration in the milk may be high, LPS is usually undetectable or in low concentration in the plasma.[260] This suggests that the fever, tachycardia, reduced rumen motility, and signs of shock that accompany severe coliform mastitis are not a consequence of endotoxemia but of production and absorption of other inflammatory mediators, such as TNF-α. The concentration of TNF-α in milk is positively correlated with coliform mastitis severity, and a high concentration of TNF-α in blood is seen only in severe responders.[25,254–256] Hematologic and plasma biochemical changes that often accompany clinical coliform mastitis include leukopenia (neutropenia, lymphopenia, monocytopenia), hypocalcemia, and reductions in plasma concentrations of zinc, copper, and iron.[126,261]

Bacteremia does not occur during experimental coliform mastitis but develops in 30% to 40% of severely ill cows with naturally occurring clinical coliform mastitis.[77,262] The risk of coliform bacteremia increases with the severity of clinical signs.[262] Also, cows that remain neutropenic for 4 or more days, or that have high metamyelocyte and myelocyte concentrations in their blood, are more likely to be bacteremic than cows with a normalizing leukon.[251] Cows with coliform bacteremia are at greater risk of death or culling compared with nonbacteremic cows.[262]

Most coliform intramammary infections are of short duration, which means that less than 5% of quarters in a herd are infected at a given time.[245,247] However, up to 10% of *E. coli* infections can become chronic. Chronic infections put cows at risk for recurrent clinical mastitis in the affected quarter and for coliform infections in other quarters.[115,263] Clinical mastitis accompanying persistent infections tends to be milder than clinical mastitis accompanying newly acquired infections.[263]

36.6.6.1

Treatment

Antibiotic treatment of subclinical coliform mastitis is considered unnecessary because of a high spontaneous cure rate and short duration of infection. The need for antibiotic treatment of clinical coliform mastitis is debated. Cows with mild to moderate clinical coliform mastitis are often able to combat the infection effectively without antibiotics. Even some systemically ill cows clear the intramammary infection rapidly, making antibiotics unnecessary. However, certain cows (e.g., immunocompromised, severely ill) are likely to benefit from appropriate antibiotic treatment.

Clinical coliform mastitis can be treated with intramammary and systemic antibiotics. Many of the intramammary antibiotics available in the United States, such as pirlimycin, erythromycin, and cloxacillin, are ineffective against coliform bacteria. Even when intramammary antibiotics with gram-negative activity

are used, most studies show no effect on mastitis outcome. For example, intramammary infusion of amoxicillin or cephapirin according to label directions (two or three treatments) did not improve clinical or bacteriologic cure rate of mild clinical coliform mastitis, compared with oxytocin injection.[214] Intramammary infusion of colistin sulfate[264] or gentamicin,[265] both of which have good activity against coliform bacteria in vitro, did not alter the course of experimental *E. coli* mastitis, compared with no antibiotics. However, intramammary antibiotic therapy was beneficial in some studies. For example, a florphenicol-containing product infused on three occasions enhanced the bacteriologic cure rate in cows with experimental *E. coli* mastitis, compared with no antibiotics.[266] In a field trial, intramammary infusion of three doses of cefuroxime was associated with a higher clinical cure rate for *E. coli* mastitis, compared with three intramammary infusions of cloxacillin, which was expected to be ineffective.[267] Benefit/cost ratios were not reported.

Systemic antibiotic therapy has been studied in many experimental coliform mastitis trials and a few field trials. Results of experimental inoculation studies must be interpreted cautiously because cows usually recover rapidly without treatment, making it difficult to determine antibiotic efficacy. Three injections of a potentiated sulfonamide did not alter the course or outcome of experimental *E. coli* mastitis compared with no antibiotics.[264] However, systemic administration of cefquinome for 2 days, with or without concurrent intramammary administration of cefquinome, improved clinical and bacteriologic cure rates and lessened milk production loss in cows with experimental *E. coli* mastitis, compared with intramammary administration of ampicillin and cloxacillin.[268] Also, two injections of enrofloxacin enhanced the rate of bacterial clearance from the mammary gland[260,269] and reduced the decline in milk yield and changes in milk composition[270] accompanying experimental *E. coli* mastitis, compared with no antibiotics. The same enrofloxacin regimen reduced the acute drop in milk yield in cows with experimental *E. coli* mastitis when the cows were also given flunixin meglumine.[271]

Results of field trials are more applicable than results of experimental inoculation trials. However, cows in field trials often receive a variety of supportive treatments and intramammary antibiotics in addition to systemic antibiotics, making it difficult to determine the direct effect of systemic antibiotic therapy. Also, it is often impossible to include an untreated control group. Some field trials have shown no benefit of systemic antibiotic therapy for clinical coliform mastitis. For example, systemic administration of gentamicin did not affect the clinical course of acute coliform mastitis, compared with no systemic antibiotics.[272] Systemic administration of ceftiofur did not improve the bacteriologic cure rate or reduce mastitis recurrence or culling risk in cows with mild coliform mastitis, compared with no systemic antibiotics.[273] On the other hand, systemic administration of ceftiofur to severely ill cows for 5 days reduced the odds of death or culling, compared with no systemic antibiotics.[274] Systemic administration of marbofloxacin for 3 days improved bacteriologic cure rate and resulted in more rapid improvement in appetite, general condition, and milk production, compared with systemic administration of amoxicillin and clavulanic acid.[275] Cows with mild to severe clinical coliform mastitis had a more rapid clinical cure when treated with intramammary (cephapirin) with or without systemic (oxytetracycline) antibiotics, compared with no antibiotics.[218]

1126

1127

Results of these studies suggest that antibiotics are not necessary or helpful for treating clinical coliform mastitis in many cases. Using antibiotics when they are unnecessary carries a risk of iatrogenic infection, is costly, and should be avoided if possible. However, cows that are unable to efficiently combat infection may benefit from antibiotics. Such cows are likely to be severely ill and have a high concentration of coliform bacteria in their milk. A high bacterial concentration indicates an inadequate neutrophil response. Therefore,

infusion of an intramammary antibiotic with a gram-negative spectrum (e.g., ceftiofur in United States, cefquinome in Europe) or systemic administration of an antibiotic that achieves therapeutic concentrations in milk (e.g., fluoroquinolones in Europe) may aid in killing bacteria and stopping the cycle of bacterial multiplication, LPS release, and worsening inflammation. Severely ill cows may benefit from systemic antibiotics to treat bacteremia and prevent infection of other organs. Unfortunately, fluoroquinolones and cefquinome, the most promising antibiotics for coliform mastitis, cannot be used in the United States; cefquinome is not available, and the use of florquinolones in lactating dairy cows is banned. The only systemic antibiotic labeled for treatment of mastitis in the United States, erythromycin, does not have an appropriate spectrum for coliform bacteria, making extralabel drug use necessary. Ceftiofur is currently the most logical antibiotic for treatment of coliform bacteremia in the United States, because potentiated sulfonamides are banned and there is a voluntary ban on aminoglycoside use in lactating dairy cows. However, the effect of systemic antibiotic administration in bacteremic cows needs further study.

Predicting which cows will be moderate responders and which will be severe responders to coliform infection would facilitate antibiotic treatment decisions. However, although cows can be distinguished on the basis of in vitro neutrophil function tests,[30] there is no practical method for use in the field. Clinical signs, blood leukocyte concentration, milk culture results, and blood culture results are currently the most predictive indicators of outcome, with clinical signs being the most practical.

36.6.6.2

Control

Control measures for coliform mastitis are similar to those for environmental streptococcal mastitis (see earlier discussion). Effort should be focused on reducing the exposure of teats to coliform bacteria during the dry and periparturient periods. Sand is the preferred bedding material because it resists the growth of coliform bacteria better than organic bedding materials.[242,276] Adding lime to the back one third of the stall reduces coliform bacteria in sawdust for 1 day but is ineffective when applied for longer periods.[277,278] The inhibiting effect of acidifying bedding conditioner is also short-lived and depends on the type of bedding used.[228]

In contrast to environmental streptococcal mastitis, intramammary antibiotic treatment at dry-off is considered to be ineffective for resolving or preventing coliform infections during the dry period. This may be a result of the antibiotics (β-lactams and macrolides) available for use in dry cows in the United States.[279] Infusion of internal teat sealant at dry-off reduced the incidence of new *E. coli* infections compared with infusion of antibiotics (cephalonium) in one study.[237] However, the risks of new gram-negative intramammary infections during the dry period and clinical mastitis during early lactation were similar when quarters were treated with teat sealant plus antibiotics (cloxacillin) or antibiotics alone.[91] The benefits of internal teat sealant are more clear-cut for environmental streptococcal mastitis.

One beneficial component of coliform mastitis control is vaccination of cows with a bacterin-toxoid derived from mutant strains of *E. coli* or *Salmonella typhimurium* that lack outer cell wall antigens. These vaccines elicit an antibody response to core LPS antigens, which is believed to facilitate opsonization and phagocytosis of gram-negative bacteria and enhance neutrophil diapedesis into the mammary gland.[280] The core antigen bacterins do not prevent intramammary infection but can reduce the incidence and severity of clinical coliform mastitis[281–284] and improve survivability.[283] The vaccines are usually administered at the end of lactation and during the dry period, to increase resistance during the periparturient period and avoid potential vaccine-induced reduction in milk production.[285] However, the optimal timing and frequency of

vaccination are still being investigated.[286] Vaccines that target receptors for iron-binding proteins on gram-negative bacteria are also being studied but have not yet been sufficiently tested in field settings.[287]

36.6.7 Coagulase-Negative Staphylococcal Mastitis

Coagulase-negative staphylococci (CNS) are the most prevalent bacteria isolated from mammary secretions of lactating cows, dry cows, and prepartum heifers (see section on heifer mastitis). Coagulase-negative staphylococci can also be isolated from teat skin and teat canals and found in the environment. *Staphylococcus hyicus, S. chromogenes, S. haemolyticus, S. epidermidis, S. simulans*, and *S. sciuri* are among the most frequently isolated CNS species, but many others have been cultured from bovine milk; *S. hyicus* is usually grouped with the CNS, even though some strains are coagulase positive.

Although the CNS are usually considered as a group, different species and strains may differ in epidemiology, virulence, and response to treatment. For example, novobiocin-sensitive CNS predominate in intramammary and teat canal infections, whereas novobiocin-resistant CNS are more likely to be found in the environment and on teat skin.[288]

Most CNS infections are subclinical, manifested only by an increase in SCC. However, infections tend to be persistent.[289] Compared with most other pathogens, the increase in SCC with CNS mastitis is much less.[200] In a meta-analysis the geometric mean SCC for CNS-infected quarters was 138,000/mL, compared with 357,000/mL for *S. aureus* and greater than 1 million/mL for *S. uberis* and *E. coli*.[290] For this reason, the CNS (as with *C. bovis*) are referred to as "minor" mastitis pathogens. Several studies suggest that CNS infection protects the mammary gland against infection with major pathogens[291,292] or shortens the duration of infection.[200] However, the protective effect differs for the various major pathogens,[292,293] and some studies have shown no protective effect or even a detrimental effect of CNS infection.[200,294] Therefore, relying on a high prevalence of CNS intramammary infections to protect a herd against major mastitis pathogens is unrealistic.

Coagulase-negative staphylococci can be isolated from the milk of cows with clinical mastitis in both poorly managed and well-managed herds.[295] However, this typically occurs in less than 10% of clinical mastitis episodes, and signs are usually mild. For these reasons, the role of CNS in clinical mastitis is usually downplayed. Care must be taken when collecting milk samples from cows with clinical mastitis to avoid culturing CNS from the skin or teat canal, which could lead to misdiagnosis.

The CNS are often susceptible in vitro to antibiotics in intramammary infusion products in the United States. Antibiotic treatment of clinical mastitis is logical, especially given the persistent nature of many CNS infections. However, controlled trials specifically investigating the efficacy and economics of antibiotic treatment for clinical CNS mastitis are lacking. Infusing intramammary antibiotics at dry-off successfully treats subclinical CNS mastitis. Treatment of subclinical CNS mastitis during lactation is unlikely to be profitable because the potential increase in milk yield after treatment is small.

There are no specific control measures for CNS mastitis. Effective germicidal teat dipping, antibiotic treatment of cows at dry-off, and prompt treatment of clinical mastitis are recommended. Although such practices can reduce the prevalence of CNS mastitis, CNS are still the most prevalent isolates in herds that have adopted these practices. Because of the wide variety of CNS and the limited economic loss associated with CNS mastitis, vaccines are not available.

36.7 OTHER MASTITIS PATHOGENS

Contagious mastitis pathogens, coliform bacteria, environmental streptococci, and CNS are responsible for most mastitis episodes in cattle. However, many other organisms are capable of opportunistically infecting the mammary gland and causing mastitis. Such infections usually occur sporadically, but herd outbreaks can develop in certain circumstances. It is not feasible to discuss all potential mastitis pathogens in detail. Some of the more common opportunistic pathogens are discussed next. In general, mastitis caused by these pathogens is not responsive to antibiotic therapy. Therefore, control depends on identifying and eliminating the source or predisposing factors for infection.

36.7.1 *Arcanobacterium pyogenes* Mastitis

Arcanobacterium pyogenes (formerly *Actinomyces pyogenes* and *Corynebacterium pyogenes*) is the predominant pathogen involved in "summer mastitis," a condition that affects prepartum heifers and nonlactating cows, mainly during summer.[296] In most cases, anaerobic bacteria (e.g., *Peptococcus indolicus, Bacteroides* species, *Fusobacterium necrophorum*) and facultative anaerobes (e.g., *Streptococcus dysgalactiae*) are also involved.[296,297] Summer mastitis occurs mainly in northern Europe and Japan, but cases have been reported throughout the world. It is characterized by a swollen, hard, painful mammary gland containing purulent, foul-smelling secretion. Acutely affected animals may show systemic signs ranging from lethargy and reduced feed intake to high fever, severe depression, abortion, and death. Chronically affected animals may have palpable or draining mammary abscesses. Systemic administration of procaine penicillin G often resolves systemic illness. However, neither systemic nor intramammary antibiotics are effective at eliminating intramammary infection.[298] The outcome of most episodes of summer mastitis is chronic clinical mastitis or a nonfunctional quarter. Therefore, affected cows are often culled.

Horn flies are believed to be responsible for transmitting summer mastitis. Flies that were allowed to feed on summer mastitis—causing bacteria transmitted the bacteria to teats, with subsequent development of intramammary infection[299]; damaged teat skin facilitated infection. However, the occasional occurrence of summer mastitis in winter suggests that other methods of transmission are possible. Because *A. pyogenes* is often found in the environment on farms and on body sites of cattle, teat skin contamination may predispose to infection, as occurs with coliform or environmental streptococcal mastitis, particularly if teat defenses are compromised.

Control of summer mastitis is accomplished by fly control, infusion of mammary glands with antibiotics at dry-off, appropriate environmental hygiene practices and stocking density, prevention and treatment of teat lesions, and prompt recognition and segregation of infected cows. Amputation of the teat, which facilitates drainage of secretions, increases environmental contamination and should not be done unless the cow can be segregated.

A condition similar to summer mastitis occurs sporadically in lactating cows.[297] *A. pyogenes* is usually involved, often in conjunction with other bacteria. Mastitis almost always follows teat injury or teat skin damage. The result is clinical mastitis and a very high SCC. Milk yield loss persists for at least 70 days.[300] The majority of episodes result in a blind quarter or loss (culling, death) of the cow.[297]

36.7.2 *Prototheca* Mastitis

Prototheca species are unicellular algae. These organisms have been isolated from bovine feces, as well as from soil, mud, vegetation, standing water, pond water, drinking water, feed troughs, and barn floors on dairy farms.[301] *Prototheca zopfii* is the main species associated with mastitis. Mastitis can be subclinical or clinical and can occur sporadically, endemically, or as an acute outbreak. Once infected, cows carry *P. zopfii* chronically in milk, mammary tissue, and supramammary lymph nodes, which results in pyogranulomatous inflammation.[302] Infected cows usually have persistently high SCC and reduced milk production. An elevation in BTSCC sufficient to threaten marketability of grade A milk has occurred in some herds.[303] Shedding of *P. zopfii* in milk can be persistent or intermittent.[304] Diagnosis is facilitated by culturing milk on selective media, such as Prototheca Isolation Medium; however, *P. zopfii* does grow on blood agar and can be detected by Gram staining of suspect colonies. Fine-needle aspiration of mammary tissue[305] and antibody testing of whey[306] are alternatives to milk culture but are not typically performed. Most *Prototheca* intramammary infections are probably acquired from the environment, but spread from shedding to uninfected cows at milking time may play a role in transmission.

Prototheca zopfii is resistant to antimicrobial therapy, and infection can persist through the dry period.[304] Therefore, identification, segregation, and progressive culling of infected animals are required to control *Prototheca* mastitis. Culling must be coupled with identification and avoidance of contaminated environmental sites, enhanced cleaning of feed bunks and watering devices, and use of milking procedures that ensure clean teats and minimize contagious spread of infection.

36.7.3 Yeast Mastitis

Yeast can be isolated from feed, bovine skin and feces, and a variety of environmental sites on dairy farms.[307] *Candida* species, *Trichosporon beigelii*, and other species can cause clinical mastitis in individual cows or herds. Yeast infection usually follows intramammary antibiotic treatment or teat skin injury. Outbreaks occur when homemade, multidose infusion products or associated equipment (e.g., needles, syringes, bottles, cannulas) are contaminated or when the teat is not adequately disinfected before infusion.[140,141] In one study, six cows treated with a homemade intramammary antibiotic solution contaminated with *T. beigelii* all developed fever, hypogalactia, and swollen mammary glands within 2 weeks, and two of the six died. When the producer continued to use homemade solutions, an additional 23 cows (over half the herd) became infected, and the herd was dispersed.[140] Yeast can be cultured from towels or teat cup liners used on infected cows, suggesting that contagious transmission may occur.[140,308]

1128
1129

On blood agar, yeast colonies appear similar to CNS colonies, so it is important to examine the colonies microscopically. Sabouraud dextrose agar with antibiotics is a common alterative medium that selects for yeasts. Yeast infections are not susceptible to antibiotic treatment, and infusion of antibiotics may potentiate infection. Antifungal agents have not been demonstrated to be effective and should not be used. Infection (especially with *Candida* species) often resolves spontaneously within 2 to 4 weeks,[141,308,309] but cows with severe or recurrent clinical mastitis, reduced milk production, or persistently high SCC should be culled.[140] Control of yeast mastitis includes aseptic intramammary infusion procedures; use of single-dose, commercially prepared antibiotic infusion products; segregation of infected cows at milking time; and use of individual rather than shared towels. Feeding contaminated silage promotes fecal excretion of yeast and has been blamed for

outbreaks of yeast mastitis in cows that have not received intramammary infusions.[308] Bulk tank SCC can increase greatly during yeast mastitis outbreaks.

36.7.4 *Pseudomonas* Mastitis

Intramammary infection with *Pseudomonas* species can result in severe clinical mastitis, similar to that caused by *E. coli*.[310] Gangrene develops in some cases.[311] However, chronic subclinical mastitis with periodic bouts of mild clinical mastitis is more common. *Pseudomonas aeruginosa* is the most common *Pseudomonas* species associated with mastitis. Intramammary infection with *P. aeruginosa* can occur sporadically or can affect more than one third of lactating cows in a herd.[312] A high incidence or prevalence of *P. aeruginosa* intramammary infections should trigger an investigation of the water system in the milking parlor. Hoses used to wash teats before milking have been implicated in numerous outbreaks of *Pseudomonas* mastitis.[313] Water from the hoses or the hoses themselves have cultured positive, particularly after water has been sitting in the hoses for several hours. When wash water is contaminated with *Pseudomonas* species, the hoses and nozzles must be replaced, but not without first culturing potential sources of bacteria. For example, water tanks, water heaters, or water lines may need to be replaced or decontaminated to prevent colonization of new hoses.[313] Other steps that can be taken are to flush stagnant water from the hoses before each milking and ensure that iodine concentration in the wash water is 25 ppm.[313] Alternatively, the teats can be predipped rather than washed before milking.

Pseudomonas mastitis has also been attributed to contaminated intramammary infusion products[314] or teat cannulas, inadequate teat end sanitation before drug infusion, contaminated teat wipes,[315] and exposure of cows to stagnant water. Therefore, investigation of a herd problem should include intramammary infusion practices and housing conditions. Once *P. aeruginosa* mastitis is established, it usually persists, and antibiotic therapy is unsuccessful. This is caused in part by production of factors that inhibit host defenses and reduce antibiotic efficacy, such as biofilm.[31] Cows with persistently high SCC or repeated bouts of clinical mastitis are usually culled, but infusing glands with germicide to induce permanent cessation of lactation is another option for cows with a single infected gland.[316]

36.7.5 *Serratia* Mastitis

Serratia mastitis is caused mainly by *S. marcescens* and *S. liquefaciens*. Mastitis can be clinical or subclinical, with the subclinical form predominating. More than 15% of lactating cows can be infected in problem herds, which can cause substantial elevation in BTSCC.[317,318] Although *Serratia* species produce bright-red colonies on blood agar, they are easily outcompeted by other pathogens. Therefore, infection prevalence may be underestimated unless special media and cultural conditions (e.g., incubation at 20° C) are used.[317,318]

Serratia intramammary infections can originate during lactation or the dry period. In one longitudinal study, 48% of *Serratia* infections were acquired during the first half of the dry period and 31% during the second half, with only 21% initiated during lactation.[319] Almost half the infections resulted in clinical mastitis. Cows with clinical *Serratia* mastitis do not exhibit severe clinical signs, such as those accompanying acute *E. coli* mastitis.[319,320] However, *Serratia* infection persists longer than *E. coli*. A mean duration of 55 days has been reported,[319] but many infections persist for 6 to 10 months.[317,321]

Serratia mastitis has been associated with contaminated teat dip or teat dip cups,[322,323] frostbitten teats,[320] contaminated organic bedding material,[317] and dirt packs in cow lots.[318] In some cases the reservoir of infection is never identified.[321] Antibiotic therapy is usually ineffective,[319,320] but some infected quarters eventually self-cure.[319] Cows with repeated bouts of clinical mastitis or persistently high SCC should be culled.

36.7.6 *Nocardia* and *Mycobacterium* Mastitis

Nocardia species occasionally cause sporadic cases or herd outbreaks of mastitis. Infections can be subclinical or clinical, with some clinical episodes being severe or fatal. Fibrosis and draining abscesses may accompany chronic infections. Clinical or subclinical mastitis can also be caused by *Mycobacterium fortuitum*. This organism causes granulomatous inflammation and encapsulated granulomas in the mammary gland.[324] Other rapidly growing *Mycobacterium* species, such as *M. chelonei, M. smegmatis, M. phlei, M. vaccae*, and *M. flavescens,* have been isolated from cows with acute or chronic mastitis.[325–327] *M. avium* subspecies *paratuberculosis,* the causative agent of Johne's disease, does not readily cause mastitis, despite being shed in the milk of infected cows.

Milk culture is required to diagnose and differentiate *Nocardia* and *Mycobacterium* species. *Nocardia* species produce characteristic cottony white, adherent colonies on blood agar, but the colonies may not appear for 72 to 96 hours; the color changes from white to yellowish orange as the colonies age. On the other hand, *M. fortuitum* produces nonadherent, smooth colonies.[324] The other mycobacteria may or may not grow on blood agar.[325,327] With all these organisms, a tentative diagnosis can be made by observing acid-fast rods or gram-positive rods with branching filaments in a milk smear.[324,325]

Nocardia species and mastitis-causing *Mycobacterium* species are saprophytes and therefore may cause intramammary infection when teats are exposed to unhygienic environmental conditions. However, most outbreaks are associated with contaminated intramammary drugs or infusion equipment or poor teat hygiene before infusion.[324,326] Results can be devastating. In one *Nocardia* outbreak, 450 of 3300 cows died, and 500 more were culled.[328] Use of oil-based dry-cow infusion products appears to facilitate growth of *Nocardia* and *Mycobacterium* species. Both types of pathogens cause intramammary infections that persist for months, even through the dry period. Antibiotic therapy is futile. Cows with chronic *Nocardia* mastitis should be culled or the quarter dried off to prevent continued exposure of humans to this potentially zoonotic pathogen.[329] Cows with *Mycobacterium* mastitis are often culled because of chronic mastitis and low productivity. Control of *Nocardia* and *Mycobacterium* mastitis involves proper intramammary infusion practices and general environmental hygiene.

1129 1130

36.7.7 *Pasteurella multocida* Mastitis

Pasteurella multocida, a normal upper respiratory tract inhabitant of cattle and contributor to the bovine respiratory disease complex, occasionally causes mastitis. Most episodes are sporadic, but herd outbreaks can occur.[330,331] In a recent report a high incidence of clinical mastitis caused by *P. multocida* was accompanied by an increase in BTSCC from approximately 200,000/mL to over 900,000/mL in about 5 months.[330] BTSCC increased partly because milk from cows with clinical mastitis was not diverted from the bulk tank. Hematogenous or lymphatic spread of *P. multocida* from the respiratory tract to the mammary gland has been proposed, and *P. multocida* has been isolated from the blood of cows with severe coliform mastitis.[262]

However, it is unlikely that hematogenous or lymphatic spread is responsible for herd outbreaks. Contamination of teats by nasal secretions (e.g., from nursing calves or intersucking cows), cow-to-cow spread at milking time, or inappropriate infusion practices may contribute to outbreaks.[330] Antibiotic treatment has historically been unrewarding, and infected cows are often culled. However, spontaneous resolution appears to occur in some cases.[330]

36.7.8 Food-Borne Disease Agents

Salmonella species and *Listeria monocytogenes* can cause mastitis. However, mastitis is an uncommon manifestation of these infections. With the exception of *Salmonella dublin*, a cattle-adapted species that is shed in the milk of infected cows, *Salmonella* species or *L. monocytogenes* in bulk tank milk are most likely to originate from unclean teats or fecal contamination of milking units, rather than from the milk itself. Good milking hygiene practices reduce the risk of milk contamination.

36.8 THERAPY OF CLINICAL MASTITIS

In the United States, farm personnel treat most episodes of clinical mastitis. The veterinarian is relied on to develop rational, economical mastitis treatment protocols for farms. Developing protocols is challenging because many factors can influence mastitis treatment decisions for a given cow. These include the severity of clinical signs; the suspected (or known) pathogen; the cow's milk production, stage of lactation, pregnancy status, and previous mastitis history; the cow's genetics and market value (if she can be culled); the price and availability of replacement heifers; the milk-withholding and slaughter-withholding times of drugs; and the anticipated treatment costs. Farm personnel responsible for making breeding and culling decisions must work with those responsible for treating mastitis to ensure that treatment decisions are financially as well as medically sound.

Even when the pathogen causing an episode of clinical mastitis is known and a logical treatment plan instituted, the outcome can vary substantially. For example, one cow with mild *Streptococcus uberis* mastitis might be clinically normal after on-label treatment with intramammary antibiotics and maintain a low SCC for the rest of the lactation. Another cow with the same signs and pathogen might take longer to respond, maintain a high SCC throughout lactation, and experience repeated recurrences of clinical mastitis. Factors responsible for intercow variability include the strain of the pathogen, inoculum dose, duration of intramammary infection at onset of treatment, and the cow's ability to mount an effective immune response. The latter is influenced by stage of lactation, parity, previous exposure to the pathogen, nutritional status, concurrent disease, and a variety of stressors. Treatment failure is often attributed to ineffective drugs when, in fact, cow or pathogen factors or how the drugs are administered may be more important.

For a mastitis treatment program to be successful, the veterinarian and producer must work together to ensure that cows are housed, managed, and fed to promote good immune function (see mastitis control section). Farm personnel must be trained to monitor cows for clinical mastitis and assess mastitis severity. Criteria must be established to assist farm personnel in selecting cows for antibiotic treatment so that time and money are not wasted on infections that are unlikely to respond. Drugs and treatment practices that are banned, ineffective, or potentially detrimental must be avoided for legal, financial, and ethical reasons. Antibiotics must have an appropriate spectrum of activity for the pathogens of concern and must be administered in sufficient doses, by the appropriate route(s), at an appropriate frequency, and for a sufficient duration to achieve the desired outcome. Appropriate supportive treatment practices must be used to promote welfare and assist the cow in responding to infection. Because of a paucity of published data to guide the veterinarian, mastitis treatment protocols are typically developed using a combination of science, personal experience, common sense, and trial and error.

36.8.1 Antibiotic Treatment

Antibiotics can be avoided without adversely impacting the outcome of many clinical mastitis episodes. However, treatment protocols that exclude antibiotic use altogether are likely to have a detrimental effect at both the cow and the herd level. Judicious use of antibiotics should be the goal, rather than complete avoidance. This section discusses some principles and factors to consider when making antibiotic treatment decisions. More specific recommendations can be found in the sections pertaining to each pathogen.

36.8.1.1 CONSIDER THE PATHOGEN

The effectiveness of antibiotic therapy and choice of antibiotic depend on the pathogen causing clinical mastitis. Cows with mild clinical mastitis and no bacterial growth in the milk are unlikely to benefit from antibiotic therapy, as are cows with a low concentration of *E. coli* in the milk. Cows with *Mycoplasma* mastitis or mastitis caused by opportunistic pathogens such as *Pseudomonas aeruginosa, Prototheca zopfii*, or yeast are unlikely to respond to antibiotic therapy. On the other hand, antibiotics can enhance resolution of many streptococcal or staphylococcal mastitis episodes.

Farm personnel can make the most informed antibiotic treatment decisions if milk from each cow is cultured. Some farms have adopted this practice, despite the associated labor and supply costs. Milk is cultured on-farm or at a local veterinary practice or laboratory. Use of biplates, triplates, or quadplates facilitates culturing and allows farm personnel or veterinary staff to identify basic classes of pathogens with minimal training. Results are usually available in 12 to 24 hours. For clinical mastitis episodes of mild to moderate severity, waiting for culture results before beginning treatment does not appear to be detrimental to the outcome.[332] Using this approach allows antibiotic therapy to be targeted to cows with gram-positive infections and can dramatically reduce antibiotic use. If farms do not routinely culture milk from cows with clinical mastitis, it is still important to determine the most frequent clinical mastitis pathogens in the herd to make appropriate treatment and prevention recommendations. It is particularly important to determine if *Mycoplasma* species or opportunistic pathogens that are nonresponsive to antibiotic therapy are contributing to clinical mastitis.

1130
1131

36.8.1.2 CONSIDER THE COW'S HISTORY

1131
1132

A small proportion of cows can be responsible for a large proportion of clinical mastitis episodes in a herd. Antibiotic therapy is unlikely to cure infections in glands with repeated bouts of clinical mastitis episodes. The same is true for cows with persistent clinical mastitis or chronic intramammary infection. A number of cow factors, such as parity, stage of lactation, and SCC, influence the outcome of antibiotic treatment for *S. aureus* mastitis (see earlier section) and probably for mastitis caused by other pathogens.

36.8.1.3 CONSIDER THE SEVERITY

Cows with severe clinical coliform mastitis have a guarded prognosis at best. Euthanasia must be considered as an alternative. However, clinical parameters such as rectal temperature, rumen contraction rate, attitude, degree of dehydration, and appearance of the mammary gland can be used to assess the likelihood of a cow returning to production.[249] A producer might be more apt to choose euthanasia over treatment if the chance of recovery is predicted to be less than 10%, versus 50%. If treatment is pursued, clinical parameters can help

determine the likelihood of bacteremia, which is an indication for systemic antibiotic use. As mentioned in other sections, the blood leukocyte concentration and the concentration of coliform bacteria in milk also reflect clinical mastitis severity and outcome. Spending a few dollars on a blood smear to determine that a cow is extremely neutropenic and unlikely to recover is more prudent than spending over $100 on aggressive treatment that fails.

36.8.1.4

CONSIDER THE ALTERNATIVES

Alternatives to antibiotic treatment include (1) euthanizing or culling the cow, (2) drying off the cow or gland, (3) inducing permanent cessation of lactation in the gland, (4) administering supportive treatment alone, or (5) doing nothing. The cow's welfare must be considered when choosing among these options, to minimize pain and suffering. If supportive treatment or no treatment is chosen, the cow should be milked after healthy cows and the milk withheld from sale as long as it is visibly abnormal. If a single gland is dried off, antibiotics should not be infused because this may result in antibiotic residues in milk from the other glands.

Germicides can be infused into the mammary gland to induce cessation of lactation. A single infusion of 120 mL of 5% povidone-iodine solution, or two 60-mL infusions of chlorhexidine diacetate 24 hours apart, induces permanent cessation of lactation.[333,334] Two infusions of chlorhexidine suspension (1 g chlorhexidine in 28 mL base) induced cessation of lactation in one study, but milk was produced by the treated quarter in the next lactation; unfortunately, 40% of treated glands were still infected when lactation resumed.[333] Researchers recommend administering a systemic antiinflammatory agent when inducing cessation of lactation, to limit the inflammatory response and reduce pain.[333] Cessation of lactation should be undertaken only if the infused gland can be clearly recognized by the milking personnel; otherwise, germicide-containing secretions could enter the bulk tank milk.

36.8.1.5

DETERMINE THE DESIRED OUTCOME

The ideal outcome of a clinical mastitis episode is clinical cure (resolution of clinical signs and return to marketable milk), bacteriologic cure (resolution of intramammary infection), and normalization of milk production and SCC. Clinical cure without bacteriologic cure can result in recurrence of clinical mastitis, transmission of infection to other glands, and persistence of high SCC, even if mastitis is caused by environmental pathogens, such as *S. uberis* or *E. coli*.[115,211,218] However, an ideal outcome is unrealistic in some cases (e.g., chronic *S. aureus* mastitis). Survival of the cow and clinical cure without bacteriologic cure may be acceptable outcomes if the intent is to slaughter or cull the cow as soon as possible or keep her until she calves or her milk production declines. Veterinarians can help producers identify appropriate goals for different types of mastitis episodes and tailor treatment recommendations accordingly.

36.8.1.6

INSTITUTE TREATMENT PROMPTLY

Antibiotic treatment is most likely to be effective if initiated early in the course of clinical mastitis. Delaying treatment for more than a few days can allow potentially susceptible pathogens, such as *S. uberis* and *S. aureus,* to become established and evade antibiotics and host defenses. If milking personnel do not strip and examine milk before each milking, mild clinical mastitis episodes may to go undetected until they are difficult to treat.

36.8.1.7

CHOOSE APPROPRIATE ANTIBIOTICS

Fluoroquinolones and potentiated sulfonamides are used to treat clinical mastitis in other countries; however, these antibiotics are banned for lactating dairy cows in the United States and must not be used, regardless of the cow's condition. Antibiotics labeled for treatment of mastitis must be used preferentially, whenever they are likely to be effective. However, extralabel drug use is frequently necessary.

The spectrum of activity must be considered when selecting an antibiotic; for example, certain β-lactam antibiotics, such as procaine penicillin G or amoxicillin, should be avoided when treating mastitis caused by penicillinase-producing staphylococci (see section on *S. aureus* mastitis). Erythromycin, pirlimycin, and penicillin, all labeled for intramammary treatment of mastitis in the United States, are not appropriate choices for coliform mastitis because coliform bacteria are resistant to these drugs. Erythromycin is the only antibiotic currently labeled for systemic administration to cows with mastitis in the United States; extralabel use of an antibiotic with a more appropriate spectrum, such as ceftiofur or oxytetracycline, is warranted for cows with severe coliform mastitis to combat potential bacteremia. When antibiotics are used in an off-label manner, extralabel drug use requirements must be observed,[335] including avoidance of violative residues in milk and meat.

36.8.1.8

REALIZE LIMITATIONS OF ANTIMICROBIAL SUSCEPTIBILITY TESTING

Antimicrobial susceptibility test results should not be used as the main basis for antibiotic selection. In most cases, susceptibility cut-points for zone diameters (for the disk diffusion test) or MIC values are based on antibiotic concentrations in serum or interstitial fluid of people after oral or intravenous (IV) dosing; these are not equivalent to concentrations achieved in milk or mammary tissue after intramammary or systemic dosing.[336] The absolute MIC value is more useful than a result (susceptible or resistant) based on an irrelevant cut-point. However, the reported MIC value may not reflect the MIC in milk because MICs in milk are often higher than in blood.[337] The newest intramammary antibiotics have MIC or disk diffusion cut-points that are relevant to treatment of mastitis, but the cut-points need to be validated in vivo. In at least two recent studies, susceptibility test results (susceptible vs. resistant) had no impact on the outcome (clinical cure, bacteriologic cure) of clinical mastitis episodes.[222,223] However, testing *S. aureus* isolates for penicillinase production facilitates antibiotic selection and prognostication; penicillinase-producing strains are less responsive to treatment even if penicillinase-resistant antibiotics are used.[148]

36.8.1.9

CONSIDER PHARMACOKINETICS AND PHARMACODYNAMICS

The site being targeted (milk, mammary tissue, or blood) influences the antibiotic treatment plan.[338] Streptococci and coagulase-negative staphylococci reside mainly in the milk, so intramammary antibiotic therapy is appropriate for mastitis caused by these pathogens; systemic antibiotics provide little or no additional benefit. On the other hand, with severe coliform mastitis, bacteria may be circulating in the blood, in which case systemic antibiotics are appropriate. With *S. aureus* mastitis and chronic *S. uberis* mastitis, organisms can reside within leukocytes and mammary tissue, as well as in milk, so a combination of intramammary and systemic antibiotics may be beneficial. Unfortunately, most of the systemic antibiotics used in lactating dairy cows in the United States, such as penicillin, ampicillin, sulfadimethoxine, and ceftiofur, do not achieve high concentrations in milk or in leukocytes. Oxytetracycline and macrolide antibiotics attain higher concentrations in milk, but mastitis pathogens are often resistant to these drugs.[338]

Time above the MIC is a critical determinant of efficacy for the antibiotics used to treat mastitis in the United States. Most intramammary antibiotics are labeled for two or three treatments 12 or 24 hours apart. This dosing regimen is highly effective for *S. agalactiae* mastitis but may not provide a sufficient duration of inhibitory antibiotic concentrations for other streptococci or staphylococci. Improved clinical and bacteriologic cure rates have been observed for *S. uberis* and *S. aureus* mastitis when intramammary antibiotics were administered for a longer duration (see sections on *S. aureus* and environmental streptococci). Switching of antibiotic classes after two or three doses, as is frequently done on farms, limits time above the MIC and should be avoided. Although extended antibiotic therapy may constitute extralabel drug use, it is more prudent than using a subtherapeutic treatment regimen.

Veterinarians can use reported MIC values and their knowledge of antibiotic pharmacokinetics and pharmacodynamics to determine if administering a particular antibiotic by a particular route is likely to exceed the MIC of a given pathogen in milk, mammary tissue, or blood. However, even if the likelihood is high, many factors can prevent effective concentrations from being achieved. For example, inflammatory debris in the ducts or microabscesses in the mammary tissue can prevent antibiotics from reaching the organisms. Factors affecting the disposition of intramammary antibiotics used to treat mastitis have recently been reviewed.[339]

36.8.1.10 SUMMARY

Judicious antibiotic use is necessary for successful mastitis treatment programs. Case selection is critically important to avoid unnecessary antibiotic use, which is costly to the producer and of concern to the public. When producers are unwilling or unable to use culture results as the basis for treatment determination, it is probably preferable to treat all cows (that meet selection criteria) with antibiotics than to avoid antibiotics altogether. In one study, cows with clinical mastitis were treated with supportive measures either alone or with antibiotics (extended intramammary cephapirin administration with or without IV oxytetracycline). Environmental (coliform, streptococcal) and bacteriologically negative mastitis episodes predominated, with the majority of episodes being mild. Antibiotic use was associated with higher clinical and bacteriologic cure rates (particularly for environmental streptococcal infections), fewer recurrences of clinical mastitis, less severe disease, lower milk yield loss (mean of 182 vs. 528 kg), and lower cost of mastitis (mean of $201 vs. $295/affected cow).[340] Complete avoidance of antibiotics can result in increased streptococcal mastitis prevalence and reduced milk quality.[211] Antibiotic selection and the timing, dosage, frequency, and duration of treatment impact the outcome. Therefore, antibiotic treatment protocols should be designed with veterinary input and monitored for efficacy. Monitoring requires that farm personnel record the incidence, severity, and duration of clinical mastitis, as well as the treatments administered; SCC data and targeted milk culture results also facilitate assessment of treatment efficacy.

36.8.2 Supportive Treatment

A variety of supportive measures are used in cows with clinical mastitis, often in conjunction with antibiotic therapy. Fluids and electrolytes are administered to combat circulatory and electrolyte disturbances. Steroidal and nonsteroidal antiinflammatory agents are used to reduce pain, inflammation, and fever. Oxytocin and frequent milk-out are used to promote milk ejection and removal of secretions. Dairy producers and veterinarians use many other systemic and local treatments, most of which have not been scientifically evaluated or shown to be effective. This section discusses the most frequently used supportive treatments.

36.8.2.1

FLUID AND ELECTROLYTE THERAPY

Cows with clinical mastitis can develop fluid and electrolyte disturbances as a result of decreased feed and water intake, rumen stasis, ileus, and diarrhea. Severely affected cows, particularly those with coliform mastitis, may develop septic or endotoxic shock; death or organ damage can result from decreased effective circulating volume.

The hydration status of an adult cow is assessed subjectively, by observing skin tent duration on the neck or eyelid and position of the globe in the orbit. Unfortunately, findings can be influenced by the body condition of the cow. Objective criteria for estimating the extent of dehydration have been reported for dairy calves[341] but have not been established for adult cows. Extrapolating from calves, a healthy cow should have a cervical skin tent duration of 2 seconds or less and no recession of the eyeball. Skin tent durations of 4, 6, or 8 seconds and eyeball recession of 2, 4, or 7 mm would correlate with 4%, 8%, and 12% dehydration, respectively. Indicators of reduced peripheral perfusion are cold extremities (ears, tail, fetlocks [only reliable at moderate ambient temperatures]) and a dry muzzle or mouth.[342] Hematocrit and plasma protein concentration are not reliable indicators of hydration status in an individual cow because of the wide range of normal values and the effects of inflammation and stage of lactation on total protein concentration.

Most cows with clinical mastitis, even severe mastitis, have normal acid-base balance or metabolic alkalosis; metabolic acidosis is uncommon and associated with a poor prognosis.[77,343] Therefore, there is no need for routine IV administration of alkalizing agents, such as bicarbonate or lactate. Also, oral products containing magnesium hydroxide or sodium bicarbonate should not be administered.

36.8.2.1.1

Oral Fluid Therapy

Fluids can be administered by the oral (intraruminal) or IV route. The oral route is least expensive and is often adequate for cows with mild to moderate dehydration. Oral fluids should be hypotonic or isotonic and should contain sodium, to create an osmotic gradient between rumen fluid and blood and enable sustained absorption of fluid and electrolytes; hypertonic oral fluids should be avoided.[344] A 600-kg cow that is 6% dehydrated needs to absorb 36 L (~9 gal) of fluid to replace her deficit. This volume can be safely administered orally, but administration of larger volumes of hypotonic fluid might lead to intravascular hemolysis.[345] Oral fluids are not sufficient for cows with severe dehydration because they do not cause rapid resuscitation.

1132

1133

36.8.2.1.2

Intravenous Fluid Therapy

Ringer's solution, which is an isotonic (isosmotic), mildly acidifying solution that contains physiologic concentrations of sodium, chloride, potassium, and calcium, is the fluid of choice for rapid IV resuscitation of adult ruminants.[344] Isosmotic (0.9%) sodium chloride is an alternative that can easily be constituted using table salt and distilled water in a sterile carboy. However, administration of isosmotic crystalloid solutions is impractical in many situations because of the large volume of fluid required and the need for IV catheterization. A 600-kg cow that is 10% dehydrated requires 60 L (~15 gal) of fluid to replace her deficit.

A practical (although inferior) alternative to isosmotic IV fluid therapy is IV administration of hypertonic (7.2%, 2460 mOsm/L) saline. Hypertonic saline is administered through a large-bore needle at 4 to 5 mL/kg body weight over 4 to 5 minutes, in conjunction with oral administration of water (5 gal). Rapid administration of hypertonic saline is required to effectively create an osmotic gradient that draws fluid from the intercellular spaces and gastrointestinal tract (mainly rumen) into the vasculature. Although hypertonic saline does not have a sustained effect and will not completely correct a large fluid deficit, it rapidly increases plasma volume and improves cardiac output and tissue perfusion. Hypertonic saline has been shown to be safe in cows with endotoxic mastitis.[346,347]

36.8.2.1.3

Electrolyte Therapy

Mild to moderate hypocalcemia often accompanies clinical mastitis, with the odds of hypocalcemia increasing with the severity of mastitis.[79] Affected cows may show muscle tremors or weakness but are seldom recumbent. Calcium supplementation can be by the oral, subcutaneous (SC), or slow IV route, depending on the severity of clinical signs and product used. Other serum electrolytes are variable. Inappetent cows often become hypokalemic, especially if anorexia persists for several days. Hypertonic saline administration also causes a transient reduction in serum potassium concentration. Potassium chloride can be supplemented orally at a rate of up to 240 g divided two to three times daily, with lesser amounts (30 to 120 g) being satisfactory for mild to moderate hypokalemia.[348] Sodium and chloride derangements are usually mild and can be addressed by administering balanced oral or IV fluids or hypertonic saline. Blood glucose concentration is usually normal or high in cows with clinical mastitis, so dextrose should not be administered routinely. However, IV dextrose treatment may be warranted in cows with concurrent ketosis.

36.8.2.2

ANTIINFLAMMATORY AGENTS

Most of the physiologic and pathologic changes associated with clinical mastitis are a result of the inflammatory response to infection. Therefore, it is logical to administer antiinflammatory agents. Also, antiinflammatory agents can reduce the pain associated with clinical mastitis. However, the inflammatory response is necessary for resolving intramammary infection, and antiinflammatory agents can produce detrimental side effects. The potential benefits must be weighed against the potential risks. Some antiinflammatory agents are expensive, making repeated doses cost prohibitive. Many of the agents used in other countries are not labeled for use in lactating dairy cows in the United States. The choice of antiinflammatory agents in the United States is limited to three approved drugs: dexamethasone, isoflupredone acetate, and flunixin meglumine.

36.8.2.2.1

Steroidal Antiinflammatory Agents

Dexamethasone and isoflupredone acetate are inexpensive steroidal antiinflammatory agents that have no milk-withholding requirement. However, each of these agents has potential adverse effects. Dexamethasone can be immunosuppressive and can cause abortion in pregnant cows, especially after 5 months of gestation. Repeated dosing (0.04 to 0.8 mg/kg IM for 3 days) of cows with subclinical intramammary infections resulted in increased bacterial shedding and development of clinical mastitis.[349,350] Isoflupredone acetate reduces plasma potassium concentration,[351] and repeated doses can lead to severe hypokalemia and recumbency.[351–353]

Data on the efficacy of steroidal antiinflammatory agents for treatment of clinical mastitis are limited to experimental mastitis trials. A single, 30-mg IM dose of dexamethasone given at the time of *E. coli* inoculation reduced local signs of inflammation, tachycardia, rumen motility impairment, and 14-day milk production loss, compared with untreated controls.[354,355] A single IM dose of a product containing dexamethasone (0.025 mg/kg) and antibiotics (colistin and ampicillin) reduced fever, improved rumen contraction rate, and shortened the duration of high SCC when given immediately or 2 hours after endotoxin infusion, but not after 4 hours[356]; this implies that delaying treatment may reduce or prevent efficacy. A single, large IV dose of dexamethasone (0.44 mg/kg) given to goats 12 hours after *E. coli* infusion reduced fever and appetite suppression but had no effect on heart rate, rumen contractions, serum biochemical parameters, SCC, milk yield, or histopathologic changes.[357] Isoflupredone acetate (20 mg IV) administered to endotoxin-challenged cows after the onset of clinical mastitis had no beneficial effect on systemic parameters, mammary gland swelling, or milk production, compared with untreated controls.[358]

The relevance of results of experimental mastitis trials to naturally occurring clinical mastitis is questionable. Thus far, published studies do not provide compelling evidence to support the use of steroidal antiinflammatory agents for treatment of clinical mastitis.

36.8.2.2.2

Nonsteroidal Antiinflammatory Agents

A variety of nonsteroidal antiinflammatory drugs (NSAIDs) are used to treat clinical mastitis worldwide. However, only flunixin meglumine is approved for use in lactating dairy cows in the United States. Dipyrone and phenylbutazone are banned, and other NSAIDs can be used in an extralabel manner only if appropriately justified. The NSAIDs are not immunosuppressive, but as with steroids, they carry a risk of abomasal ulceration and renal damage. These complications are not well documented in cattle and presumably are minimized if treatment is of short duration, hydration is maintained, and appetite is restored.

Treatment of cows with flunixin meglumine at 0 and 3 to 5 hours after *E. coli* inoculation abolished fever and improved rumen motility, compared with untreated controls, but had no effect on gland or milk appearance, heart rate, or respiratory rate.[359] Similarly, administration of flunixin meglumine every 8 hours beginning 2 hours after endotoxin infusion reduced fever and improved gland appearance and attitude, compared with untreated controls, but had no effect on milk appearance, heart rate, rumen motility, SCC, or milk production.[360] When administered after the onset of fever and gland swelling, flunixin meglumine (2.2 mg/kg IV) reduced heart rate and rectal temperature and increased rumen motility in cows with endotoxic mastitis but had no effect on milk production or mammary gland inflammation.[361] As with the steroids, the relevance of these trial results to cows with naturally occurring clinical mastitis is uncertain.

The most compelling evidence to support the use of NSAIDs in clinical mastitis comes from field trials. In one trial, cows treated with NSAIDs (ketoprofen, 2 g IM; dipyrone, 20 g IM; or phenylbutazone, 4 g IM) plus systemic antibiotics were 2.8 times more likely to recover (return to ≥75% milk production) than cows treated with antibiotics alone.[362] In two trials, cows treated with antibiotics plus ketoprofen (2 g once daily) were 2.6 and 6.8 times more likely to recover than cows treated with antibiotics alone or in conjunction with a placebo.[363] Meloxicam, although not available for use in U.S. cattle, was shown to reduce pain associated with clinical mastitis.[364] In summary, it appears that NSAIDs can improve well-

1133
1134

being and outcome in cows with clinical mastitis. However, specific criteria for instituting NSAID therapy and the optimal duration of treatment remain to be determined.

A locally infused antiinflammatory agent (glycyrrhizin) reduced inflammatory changes in the mammary gland and milk of cows with coagulase-negative staphylococcal mastitis, compared with intramammary antibiotics.[365] However, such antiinflammatory agents require additional study in controlled field trials.

36.8.2.3

OXYTOCIN AND FREQUENT MILK-OUT

Oxytocin is administered to stimulate milk ejection and facilitate removal of secretions from mastitic mammary glands. Frequent milk-out (stripping) is performed to increase the frequency of removal of pathogens, toxins, and inflammatory mediators from the mammary gland. Although seemingly logical practices, no solid evidence exists to support their routine use, and some data suggest they can be detrimental. Oxytocin (20 IU IM twice daily for 3 days) at milking time prevented development of clinical mastitis in only two of eight cows experimentally inoculated with *Streptococcus uberis;* once clinical mastitis developed, oxytocin was ineffective at resolving the *S. uberis* infections.[219] When initiated at the onset of clinical *S. uberis* mastitis, oxytocin (80 IU IM, followed by 20 IU IM twice daily) resulted in no clinical or bacteriologic cures by 3 or 6 days.[217] In contrast, clinical and bacteriologic cure rates of 91% and 64%, respectively, were achieved by intramammary antibiotic administration for 6 days. When oxytocin was used in conjunction with intramammary antibiotics, clinical and bacteriologic cure rates at 6 days dropped to 10%, implying a significant adverse effect of oxytocin and stripping. Frequent milk-out (every 4 to 6 hours) in conjunction with oxytocin administration did not shorten the time to clinical or bacteriologic cure or resolution of systemic illness in cows with experimentally induced coliform mastitis, compared with no treatment.[366] When oxytocin administration (100 IU IM twice daily for 1 week) was compared with no treatment (udder massage only) in cows experimentally inoculated with *Staphylococcus aureus*, oxytocin administration reduced bacterial concentrations in the milk but did not improve the bacteriologic cure rate or reduce SCC.[367] Oxytocin administration increases the permeability of mammary epithelial tight cell junctions in a dose-dependent manner, which can alter milk composition in nonmastitic glands, particularly if high doses (≥100 IU) are administered repeatedly.[368]

Oxytocin and frequent milk-out have not been evaluated extensively in the field. In a California study, oxytocin (100 IU IM twice daily for three treatments) at milking time resulted in similar clinical and bacteriologic cure rates, as did two or three treatments with intramammary antibiotics; however, an untreated control group was not evaluated.[214] No overall benefit resulted because the oxytocin-treated cows had a higher recurrence rate of clinical mastitis, particularly environmental streptococcal mastitis.[215] In a Virginia study, frequent milk-out (six times daily) in conjunction with oxytocin administration (20 IU) did not improve clinical or bacteriologic cure rates, time to cure, or return to milk production compared with no treatment.[369] In an Illinois herd, cows treated with supportive therapy alone (oxytocin administration [all cases], frequent milk-out [moderate and severe cases], antiinflammatory therapy [severe cases], and fluid therapy [severe cases]) had lower clinical and bacteriologic cure rates and a higher recurrence rate than cows given antibiotics in addition to the same supportive therapy.[218]

In summary, oxytocin administration and frequent milk-out do not appear to be effective stand-alone treatments for clinical mastitis, particularly mastitis caused by streptococci, and may even be detrimental. In certain circumstances, when a cow clearly will not eject milk or when garget in the milk prevents effective

milk removal, these practices might be of some benefit. Otherwise, unnecessary administration of injections and frequent milking of painful teats should be avoided for welfare reasons.

36.8.2.4 OTHER SUPPORTIVE TREATMENT MEASURES

A wide variety of other nonantibiotic supportive measures are used to treat cows with clinical mastitis. These include udder massage, application of liniments, hydrotherapy of the affected gland, intramammary infusion of fluids, vitamin injections, and homeopathic treatments. In most cases, efficacy has not been scientifically evaluated, or the only studies involved experimentally induced mastitis, making it difficult to extrapolate results to naturally occurring clinical mastitis. Massage and liniment application were of no benefit in resolution of experimental *S. aureus* infection.[367] Intramammary administration of hypertonic saline did not hasten recovery of cows with experimental coliform mastitis.[370] Ascorbic acid (25 mg/kg SC once daily for 5 days) in conjunction with intramammary antibiotic therapy appeared to shorten recovery time and reduce severity of illness in one small field study, compared with intramammary antibiotics alone.[371] Ascorbic acid, 25 g IV 3 and 5 hours after intramammary endotoxin infusion, did not reduce clinical illness but did increase milk production recovery (9% higher).[372] Homeopathy is frequently practiced on organic dairy farms, but controlled clinical trials are difficult to perform because of the individual nature of the treatments; minimal efficacy data are available.[373] Natural antimicrobial substances (e.g., lactoferrin, nisin) and immunostimulants are receiving attention as potential alternatives or adjuncts to antibiotic therapy but need further investigation. Minimizing stress, feeding balanced diets with appropriate concentrations of vitamins and minerals, and maintaining cows in good nutritional condition are logical practices that should enable cows to respond effectively to clinical mastitis.

36.9 MASTITIS IN HEIFERS

Mammary glands of prelactational heifers are often infected with mastitis pathogens. The prevalence of intramammary infection can be as high as 90% to 97% of heifers and 60% to 75% of quarters.[374,375] In a multistate study the prevalence of intramammary infection in heifers at calving averaged 34% of quarters and 63% of heifers, but varied widely by location and herd.[376] Prevalence appears to be highest during the third trimester of gestation.

Coagulase-negative staphylococci are responsible for the majority of intramammary infections in heifers. However, *Staphylococcus aureus* can be isolated from up to 37% of heifers and 15% of quarters,[374] which allows heifers to serve as a reservoir of *S. aureus* for lactating cows. In most herds the prevalence of *S. aureus* intramammary infections in heifers is between 0% and 25%.[85,377] Other pathogens isolated from mammary secretions of heifers before or at calving include environmental streptococci and, occasionally, *Streptococcus agalactiae* and coliform bacteria. The majority of intramammary infections are subclinical, but when clinical mastitis is present at calving, the outcome is often poor, especially if mastitis is caused by *S. aureus*.[378]

1134

1135

The mechanisms by which the mammary glands of heifers become infected are uncertain. Coagulase-negative staphylococci and *S. aureus* can be isolated from teat skin, teat orifices, and teat canals of prepartum heifers,[379,380] suggesting that intramammary infection follows colonization of the skin and canal. In fact, heifers with teat skin colonized by *S. aureus* before calving tended to be at higher risk of *S. aureus* intramammary infection at calving.[379] On the other hand, isolation of *S. chromogenes* from the teat apex did not increase intramammary infection risk at calving but did increase the likelihood that the heifer would have a low SCC (<200,000/mL).[381] *S.*

aureus was more frequently isolated from heifer body sites, such as udder skin, muzzle, and vagina, and from insects, bedding, water, and the environment in herds with a high *S. aureus* prevalence (>10%) in lactating cows, compared with herds with a low prevalence (<3%).[379]

The feeding of infected milk to calves may facilitate colonization of the oral cavity or muzzle.[379] Intersucking occurs frequently among calves and heifers[382] and may transmit pathogens from the oral cavity or muzzle to the teat skin. However, flies are thought to be more important than intersucking in infection transmission. DNA fingerprinting identified the same *S. aureus* subtypes in horn flies found on heifers as in the mammary secretions and teat canals of the heifers.[383] When flies exposed to a marker strain of *S. aureus* were housed with heifers, the same strain was subsequently isolated from teat skin of the heifers.[384] Teats with visible scabs or lesions have a higher prevalence of intramammary infection than normal teats,[380] and scabs can harbor high concentrations of *S. aureus* and serve as a source of infection for flies.[384]

36.9.1 Treatment

Several studies have investigated the efficacy and cost-effectiveness of intramammary antibiotic treatment in prepartum heifers. One treatment option is to administer an intramammary antibiotic formulated for dry cows to breeding age or primigravid heifers. A dry-cow formulation of penicillin and novobiocin reduced infection prevalence from 98% (prepartum) to 40% (at calving), with prevalence in untreated heifers remaining above 95%.[385] In the same study, *S. aureus* prevalence decreased from 17% to 3% of heifers after treatment, compared with a lesser decrease (26% to 16%) in untreated heifers. When quarters were inoculated with *S. aureus* 12 to 14 weeks before calving, infusion with a dry-cow formulation of cephapirin 1 to 3 weeks later cured all treated quarters, compared with spontaneous cure in only one of nine untreated quarters.[386] The choice of antibiotic appears to be relatively unimportant, because high overall cure rates were observed for five different dry-cow products infused 12 to 14 weeks prepartum.[387] However, the timing of treatment is important, with fewer new infections developing after treatment during late gestation.[387]

The other treatment option is to administer an intramammary antibiotic formulated for lactating cows 7 to14 days before calving. This is generally more practical because heifers are managed more intensively during the close-up period than earlier in gestation. When lactating cow formulations of cloxacillin or cephapirin were infused in this manner, the prevalence of intramammary infection after calving was 18% of heifers and 5% of quarters, compared with 78% of heifers and 45% of quarters in untreated controls.[375] Lactating formulations of penicillin-novobiocin and pirlimycin, administered prepartum, also significantly reduced intramammary infection prevalence in heifers at calving.[388] Treatment 14 days before the expected calving date reduces the risk of violative antimicrobial residues in milk after calving, compared with treatment 7 days before the expected calving date.[389]

Advantages of prepartum antibiotic treatment of heifers include a higher cure rate than with treatment during lactation (especially for *S. aureus*), a reduction in chronic mastitis, a lower SCC in cured quarters, and reduced risk of pathogen transmission to other cows or quarters.[390] Antibiotic-treated heifers produced 531 kg more milk/lactation than untreated heifers in one study,[390] but no difference in milk yield or SCC was found in other studies.[376,391] Prepartum antibiotic treatment is most appropriate for herds with a high prevalence of *S. aureus,* high SCC, or high incidence of clinical mastitis in heifers at calving. Extreme care must be taken to disinfect teat ends thoroughly before infusing antibiotics, to avoid iatrogenic infections. Control measures should focus on fly control and reducing the incidence and prevalence of *S. aureus* intramammary infections in lactating

cows. Feeding milk replacer or pasteurized waste milk may reduce the risk of colonization of calves with *S. aureus* in problem herds, but the impact on subsequent mastitis incidence is uncertain.

36.10 ECONOMIC IMPACT OF MASTITIS

Mastitis is considered the most costly disease of dairy cattle. The costs associated with mastitis are a result of unearned revenues as well as real expenditures. Costs differ for subclinical and clinical mastitis and depend on market prices for milk and cattle, the causative pathogen, and the parity and stage of lactation of the cow.

36.10.1 Subclinical Mastitis

In most prevalence surveys, approximately one third to one half of cows have intramammary infections, with the vast majority of infections being subclinical. Subclinical infection is accompanied by an increase in SCC and reduction in milk yield, the extent and duration of which depend on the causative pathogen and effectiveness of host defense mechanisms. The reduction in milk yield associated with subclinical mastitis is usually estimated by extrapolating from crude SCC or a logarithmic transformation of SCC. The relationship between crude SCC and milk yield loss is nonlinear, whereas logarithmic transformation results in a linear relationship. For example, each twofold increase in crude SCC above 50,000/mL on monthly test day reports was associated with an average reduction in milk yield of 0.6 kg/day for multiparous cows and 0.3 kg/day for heifers.[392] Each unit increase in $\log_{10}$SCC on weekly test day reports was associated with an average reduction in milk yield of 2 kg/day for multiparous cows and 1.3 kg/day for heifers.[393] In the United States, linear score (LS), a $\log_2$-based transformation of SCC that results in scores of 0 to 9, is the usual parameter used. Each unit increase in lactational average LS above 2 results in an average milk yield reduction of 0.7 kg/day or 180 kg/lactation for multiparous cows, with losses for heifers being approximately half.[394] Such associations provide a rough estimate of the magnitude of milk yield loss associated with subclinical mastitis in a herd, but do not accurately estimate milk yield loss in individual cows.

Sometimes, herd milk yield loss is estimated from the SCC of the bulk tank (BTSCC). For example, a decrease in milk yield equating to a loss of at least $100/cow/year was demonstrated in herds with BTSCC greater than 200,000/mL.[395] One problem with using BTSCC to estimate milk yield loss is the dilutional effect of milk from high-yielding cows on BTSCC.[396] 1135 1136

Milk from cows with subclinical mastitis is not usually withheld from the bulk tank. This causes an increase in BTSCC and reduction in milk quality. The milk quality changes associated with subclinical mastitis adversely affect the processing properties, organoleptic qualities, and shelf life of milk and milk products.[397] In the United States, milk processors routinely monitor BTSCC, and dairy producers may be paid premiums for low BTSCC or penalized for high BTSCC. Premium and penalty programs vary widely by location; however, in some cases, penalty payments or unearned premiums account for the greatest loss associated with subclinical mastitis.[398] A substantial economic loss is incurred when BTSCC exceeds 750,000/mL because the milk cannot be marketed as grade A; this BTSCC limit is much higher in the United States than in Canada and other developed countries.[399] High-BTSCC milk also has a greater risk of condemnation because of violative antimicrobial residues.[400–402]

Cows that maintain persistently high SCC, have untreatable intramammary infections, or have low milk production often are culled prematurely. The cost of premature culling depends on the perceived value of the cow, the market prices for culled cows and replacement heifers, and the potential value of the replacement

heifer.[398] A recent retrospective study revealed that cows with lactation average SCC greater than 700,000/mL had more than twice the risk of being culled than cows with SCC of 200,000 to 250,000/mL; the risk tended to be greater in herds with low SCC than those with high SCC.[403] Cows that are not culled sometimes require segregation or special milking procedures that increase labor costs; for example, cows with chronic *S. aureus* or *Mycoplasma* mastitis may need to be milked last or in separate strings.

36.10.2 Clinical Mastitis

Approximately 15% to 20% of cows experience clinical mastitis during the course of a lactation.[404,405] However, the incidence of clinical mastitis varies among herds, from less than 10% of lactations to greater than 50% of lactations. An acute drop in milk production often accompanies the onset of clinical mastitis. Some cows rapidly cease lactating or produce substantially less milk than predicted for the rest of the lactation. Others experience little drop or rapidly return to normal or near-normal production.[406] Average lactational milk yield losses reported for clinical mastitis range from less than 50 kg to 749 kg per lactation, but a loss of 5% of lactational milk production is usually assumed.[406] Milk yield loss is generally higher when clinical mastitis occurs in early to peak lactation than in late lactation, and for multiparous cows than for heifers.[406]

Milk that is visibly abnormal or contains drug residues must be diverted from the bulk tank and withheld from sale. The cost associated with diverted milk is a major component of the cost of clinical mastitis. Actual cost depends on whether the milk is discarded or fed to calves in place of milk replacer, as well as the price of milk and milk replacer and difference in labor associated with the two feeding methods. Failure to detect clinical mastitis and divert milk from the bulk tank adds to the reduction in milk quality caused by subclinical mastitis. Cows with repeated episodes of clinical mastitis produce the majority of diverted milk in some herds.[407]

A small proportion (<5%) of cows with clinical mastitis die or are euthanized because of the severity of their condition. More cows fail to respond adequately to treatment or experience recurrent episodes of clinical mastitis, resulting in premature culling. Mastitis is consistently ranked as one of the top reasons for culling dairy cows. In a national survey, U.S. dairy producers reported that mastitis and other udder problems were responsible for an average 27% of culls[408]; mastitis may also have contributed indirectly to the 19% of cows culled because of low milk production. Neerhof et al.[409] reported that the risk of culling Danish Black and White cows was 1.7 times higher for cows that had experienced clinical mastitis than for those without mastitis. Rajala-Schultz and Gröhn[410] reported similar findings for Finnish Ayrshire cows. In a study examining the effect of mastitis on herd life in two New York dairy herds, the first episode of clinical mastitis caused by *Streptococcus* species, *S. aureus, Staphylococcus* species, *E. coli*, or *Klebsiella* species reduced herd life, with pathogen-associated hazard ratios ranging from 1.19 to 3.18.[411] The hazard of culling for clinical mastitis differs with stage of lactation and increases with age of the cow.[411,412]

The cost of diagnosing and treating an episode of clinical mastitis depends on its severity, the causative pathogen, the treatments administered, the labor required, whether the milk is cultured, and whether a veterinarian is involved. Antibiotic treatment carries a risk of inadvertently introducing antibiotics into the bulk tank and causing violative drug residues, which is costly. However, if antibiotic treatment improves the cure rate and reduces lost milk, SCC, and risk of mastitis transmission, economic losses are reduced.[413] The appropriate selection of cases for antibiotic treatment is critical for optimizing returns and avoiding unnecessary losses, as discussed in other sections.

36.10.3 Effects of Mastitis on Reproduction

One increasingly recognized cost associated with mastitis is reduced reproductive performance. Development of clinical mastitis between days 15 and 28 postpartum delayed the onset of ovarian cyclicity and estrus by approximately 6 days, regardless of the causative pathogen (gram positive or gram negative).[414] Clinical mastitis episodes caused by gram-negative pathogens induced a substantially higher rate of premature luteolysis (47%) than those caused by gram-positive pathogens (8%) and prolonged the follicular phase of the estrus cycle when mastitis occurred at that time.[414] Development of clinical or subclinical mastitis before first service caused increases in days to first service, days open, and services per conception, compared with nonmastitic cows.[415] Induction of *S. uberis* mastitis before ovulation decreased luteinizing hormone (LH) pulses, impaired 17β-estradiol production, and prevented ovulation.[416] Maintenance of pregnancy can be impaired when mastitis occurs shortly after a cow is bred, presumably as a result of embryonic death.[417,418] Cows with LS greater than 4.5 before breeding were 2.4 times more likely to experience early embryonic death than cows with LS less than 4.5.[419] Both experimental and natural clinical mastitis episodes have been reported to induce abortion.[420,421] Together, these findings imply that both clinical and subclinical mastitis caused by a variety of pathogens can be detrimental to reproductive performance and can contribute to economic loss.

36.10.4 Total Cost of Mastitis

The total cost of mastitis is impossible to quantify accurately, varies over time, and is herd dependent. No studies have included all the major categories of economic loss in their calculations.[406] However, imperfect estimates of average costs have been generated and are useful for appreciating the impact of the disease. The cost of clinical mastitis has been estimated at $107 per case[422] and $30 to $50 per cow in the herd.[398] In one herd the cost associated with loss of saleable milk and treatment alone averaged $201 or $295 per lactation, depending on the treatment protocol.[340] The total cost of mastitis has been estimated at $200/cow/year or $1.5 to $2 billion per year nationally.[398,423]

1136 1137

The economic loss resulting from mastitis is not equivalent to the economic returns available from mastitis control, because it is impossible to eliminate mastitis completely. Also, the costs associated with mastitis control can be substantial. In one survey the cost of mastitis prevention accounted for 50% of the cost for preventing all diseases.[422] Return on investment in mastitis control measures is more important than the absolute cost. Return on investment ranged from −$20 to $275/cow/year in nine studies,[424] depending on the prevalence and type of mastitis in the herd, control measures already in place, efficacy of the control measures to be implemented, and producer compliance.[425,426]

Stochastic modeling has been used to predict return on investment under a variety of scenarios.[426,427] Using one model, mastitis control programs that included antibiotic treatment of all cows at dry-off and preventive measures in the milking parlor (forestripping, cleaning, or predipping of teats and postdipping of teats), with or without antibiotic treatment of lactating cows, yielded positive annual net benefits, regardless of whether the primary pathogens in the herd were contagious or environmental. On the other hand, lactating-cow antibiotic therapy alone was not profitable in any circumstance.[426] Such models can assist in making rational decisions about mastitis control, but results depend on the assumptions used, which are seldom universally applicable.

36.11 MASTITIS CONTROL

Eradication of mastitis is an unrealistic goal. However, mastitis can be controlled by (1) determining the causative pathogens, (2) identifying and reducing the predominant reservoirs, (3) identifying and limiting the main risk factors for transmission, and (4) promoting host defense. Control measures for specific pathogens are discussed in previous sections. Pathogen identification is an essential first step in mastitis control because reservoirs and risk factors differ among mastitis agents. Reducing reservoirs and risk factors can decrease intramammary infection risk, but exposure of teats to pathogens cannot be completely avoided. Therefore, host defense mechanisms are critically important in preventing new infections and limiting the severity and duration of mastitis (see section on defense mechanisms).

Factors influencing host defense against mastitis include teat condition, nutrition, genetics, and stress. Traditional mastitis control measures can be augmented by keeping teats healthy, feeding appropriately formulated diets, selecting for inherent mastitis resistance, and minimizing stress.

36.11.1 Teat Condition

Teat injuries can be avoided through appropriate housing and stall design. Milking machine—associated teat damage can be minimized by providing appropriate pulsation and teat end vacuum and by using properly sized teat cup liners. Premilking teat preparation methods can promote oxytocin release and allow teat cups to be attached after milk ejection, thus minimizing milking time and associated risks to the teats. Teat chapping, which facilitates bacterial colonization, can be avoided by providing protection against adverse weather and using teat dips that condition the skin. Teat cannulas and dilators compromise the teat canal and should be avoided. Intramammary antibiotics should be administered using the partial-insertion method of infusion.[14] Internal teat sealant can enhance physical defense against pathogen invasion during the dry period.

36.11.2 Nutrition

Negative energy balance, or more specifically *ketogenesis,* is a risk factor for mastitis.[428,429] Ketone bodies adversely affect neutrophil function in vitro.[430] Experimental *E. coli* mastitis is more severe in ketonemic cows than nonketonemic cows.[429,431] In one field study, 29% of cows with circulating β-hydroxybutyrate (BHB) concentration of 1400 μmol/L or greater in the week before calving developed clinical mastitis after calving, compared with 9% of cows with BHB concentration less than 1400 μmol/L.[432] In another study, cows with serum BHB concentration of 1000 μmol/L or greater 1 to 3 days after calving were at increased risk of developing clinical mastitis caused by environmental pathogens, compared with cows with BHB concentration less than 1000 μmol/L.[433] Heifers with BHB concentration of 100 μmol/L or greater in milk during the first or second week after calving were more likely to have subclinical mastitis before calving and develop new intramammary infections after calving, compared with heifers with less than 100 μmol/L BHB in milk.[434] These findings suggest that dietary management to minimize ketosis in the periparturient period should reduce the incidence and possibly the severity of mastitis. Ionophore antibiotics also may help to reduce energy-associated mastitis risk. Administering a controlled-release monensin-containing capsule before calving reduced serum BHB concentration in periparturient cows,[435] and feeding monensin after calving reduced clinical mastitis incidence and rate of intramammary infection.[436]

Dietary vitamin and mineral concentrations influence mastitis susceptibility, particularly in the periparturient period when feed intake declines. Vitamin E and selenium have received the most attention because of their synergistic antioxidant actions and beneficial effects on the immune system, especially neutrophil function.[437,438] Heifers fed a selenium-deficient diet before and during their first lactation experienced more severe and persistent *E. coli* mastitis than heifers fed a selenium-supplemented diet.[439] The prevalence of intramammary infection, rate of clinical mastitis, and BTSCC all decline as blood selenium concentration increases.[437,440] Supplementing 1000 or 4000 IU vitamin E/day during the last 2 weeks of the dry period reduced clinical mastitis in the first week after calving by 30% and 88%, respectively, compared with 100 IU/day.[441] Current recommendations are to feed 1000 IU vitamin E/day during the late dry period and early lactation and 500 to 1000 IU/day at other times.[442] The traditional practice of feeding 0.1-ppm dietary selenium may result in blood selenium concentrations that are too low to protect against mastitis; 0.3 ppm is considered advantageous.[441] Rations for U.S. dairy cows often contain suboptimal concentrations of both vitamin E and selenium, which creates an opportunity to improve mastitis resistance through dietary supplementation. In contrast, parenteral injection of vitamin E or selenium provides less consistent beneficial effects.[437,443]

Additional dietary ingredients considered important in immune system function and mastitis resistance are vitamin A, β-carotene,[444] and antioxidant trace minerals and vitamins such as zinc, copper, and ascorbic acid.[445] Ensuring adequate vitamin and micronutrient supplementation should assist in mastitis control. Protein balance, particularly a balance of amino acids such as glutamine, may also be important.[446]

1137

1138

36.11.3 Genetics

Although mastitis occurrence is largely determined by physiologic and environmental factors, susceptibility is partly attributable to genetic variability. Direct selection against clinical mastitis is difficult because heritability is low (<0.05) and producers do not consistently record clinical mastitis events. Somatic cell count (SCC) is recorded more consistently and has higher heritability (0.10 to 0.30), making it a better selection parameter.[447] Genetic correlation between SCC and intramammary infection is almost 1.0, and correlation between SCC and clinical mastitis is fairly high (0.5 to 0.8), making SCC a reasonable proxy.[448] For instance, daughters of sires that transmit low somatic cell score (SCS) have a lower prevalence of intramammary infection at first parturition and shorter and less severe episodes of clinical mastitis during first lactation than daughters of sires that transmit high SCS.[449,450] Lactation average SCS, clinical mastitis incidence, and duration of clinical mastitis in first lactation are all influenced by predicted transmitting ability (PTA) for SCS, as are total number of lactations, days of productive life, and total days in milk, which means that daughters from sires with high PTA SCS are culled sooner.[451] The concern that breeding for low SCS will increase clinical mastitis susceptibility does not appear to be founded.[452]

Both clinical mastitis and SCC are moderately correlated (0.2 to 0.7) with udder depth and udder attachment, meaning that selecting for high, tightly attached udders should reduce mastitis susceptibility.[448] Clinical mastitis is negatively correlated with body condition score (−0.16) and positively correlated with dairy character (0.27), which suggests that placing more emphasis on body condition and less on dairy character might promote positive energy balance and reduce the risk of ketosis-associated mastitis.[453]

Unfortunately, clinical mastitis is positively correlated (~0.40) with milk production and milking speed.[448] Therefore, selecting solely for increased milk production is detrimental to udder health.[454] This may be the result of shorter, wider teat canals and increased pressure in the teats of high-yielding cows, both of which compromise the barrier function of the teats. Use of bovine somatotropin (rBST), which enhances milk yield, increases the risk of clinical mastitis by approximately 25%.[455] High-yielding cows also have more severe negative energy balance in the periparturient period, when immune function is compromised and mastitis risk is high.[429] Therefore, the economic benefits of higher production and faster milking must be weighed against the economic and welfare costs associated with clinical mastitis.

It may be possible to use immune function measures to select for mastitis resistance. Neutrophil function in vitro and antibody production in response to vaccination in vivo are more heritable than SCS and influence mastitis susceptibility or severity.[448,456] Therefore, immune function testing of sires might be helpful in selecting for cows that can resist mastitis. Differences in alleles of class I and class II major histocompatibility complex (MHC) genes also are associated with clinical mastitis susceptibility or SCC. For example, MHC class I alleles A26 and A7(w50) are associated with mastitis resistance and the class II DRB3.2*24 allele with susceptibility.[448] Similarly, quantitative trait loci for SCS and clinical mastitis are found on almost all chromosomes.[448] Therefore, in the future, producers may be able to use haplotype or quantitative trait loci data to supplement other selection criteria. The challenge will be to develop the most appropriate combinations of criteria to protect udder health without serious detriment to other health or production parameters.

36.11.4 Stress

Mastitis susceptibility is increased in the periparturient period, when stress hormones are high. The role of stress at other times on mastitis susceptibility is not clear. However, because a variety of stressors affect immune function, it is logical that stress avoidance should promote mastitis resistance. Such measures as sprinklers, shades, and tunnel ventilation can help prevent heat stress. Good housing and stall design, appropriate stocking density, and sufficient feedbunk space can reduce housing and social stress. Handling cows calmly and humanely, taking advantage of natural behaviors, can minimize handling stress.

36.11.5 Other Practices That Influence Host Defense

Vaccination of cows against core LPS antigens boosts immunity against gram-negative pathogens and reduces the severity of coliform mastitis. Unfortunately, effective vaccines are not available for most mastitis pathogens. Manipulation of photoperiod (short daylength exposure) during the dry period enhances cellular immune responses in vitro at calving,[457] but the effect on mastitis incidence and severity needs further investigation.

Antibiotic therapy can assist host defenses in resolving mastitis in some cases (e.g., with streptococcal infection). However, several classes of antibiotics often used to treat mastitis, such as β-lactams and tetracyclines, have detrimental effects on neutrophil phagocytosis or killing ability in vitro.[26,458] It is not known if this translates to a negative impact on mastitis outcome in vivo.

36.12 MASTITIS IN SHEEP AND GOATS

36.12.1 Clinical Mastitis

The incidence of clinical mastitis in small ruminants is low (<5% of lactations).[459] In most cases, clinical mastitis is sporadic, but outbreaks occasionally occur. Ewes or does with clinical mastitis can experience severe clinical illness or develop chronic mastitis with abscessation. The reduction in milk yield that accompanies clinical mastitis reduces income on dairy operations and can adversely impact growth or viability of nursing neonates. Dairy producers must divert clinically abnormal or residue-containing milk from sale. Ewes or does that develop clinical mastitis are often culled at weaning or at the end of lactation, if not sooner. Therefore, despite its low incidence, clinical mastitis can still have an adverse economic impact on sheep and goat farms.

Staphylococcus aureus is the most common clinical mastitis pathogen in meat and dairy sheep, as well as in goats.[460,461] *S. aureus* is more likely to cause severe clinical signs or gangrenous mastitis in small ruminants than in cattle, and small ruminants are more likely to develop abscesses in the mammary gland if infection persists. Another important clinical mastitis pathogen of sheep, particularly meat sheep, is *Mannheimia haemolytica* (formerly *Pasteurella haemolytica*).[460] *S. aureus, M. haemolytica*, and coagulase-negative staphylococci are responsible for most clinical mastitis episodes in sheep, with streptocooci, corynebacteria, coliform bacteria, and *Arcanobacterium pyogenes* isolated less frequently.[460] These pathogens also cause clinical mastitis in goats, but *M. haemolytica* is isolated less frequently than in sheep.[459] Outbreaks of clinical mastitis in small ruminants are usually caused by *S. aureus*, streptococci, or opportunistic pathogens, such as *Pseudomonas* or fungi.[459]

When clinical mastitis cannot be explained by bacterial or fungal infection, *Mycoplasma* infection should be suspected. A variety of *Mycoplasma* species can cause clinical mastitis outbreaks in small ruminants. *Mycoplasma mycoides* subspecies *mycoides* (large-colony type) is an important mastitis pathogen in goats in the United States, especially in California.[462,463] *Mycoplasma putrifaciens* is involved in some outbreaks,[464] and *M. agalactiae* is isolated on rare occasions.[465] Does with *Mycoplasma* mastitis often exhibit severe clinical illness and reduced milk yield, in addition to an inflamed udder and visibly abnormal milk; however, subclinical intramammary infections can occur. Adult goats and kids in herds with *Mycoplasma* mastitis may experience polyarthritis and pneumonia, and pregnant does may abort. Morbidity and mortality can be very high, with more than 90% of goats dying or euthanized in some herds.[464]

Clinical mastitis is detected at milking time in dairy sheep and dairy goats but may not be readily apparent in animals that nurse their young. Lethargy, depression, or abnormal gait may be the most obvious sign if the mammary gland is not greatly enlarged. Abnormal gait, which is often mistaken for lameness, occurs when the animal attempts to keep its hindlimb away from the painful gland. Lambs or kids of dams with clinical mastitis may make frequent attempts to nurse but have poor abdominal fill because of the reduced milk production.

Little research has been done on the treatment of clinical mastitis in small ruminants. Ewes or does with severe or recurrent clinical mastitis are often sacrificed rather than treated, and the goal of treatment is often to maintain survival until the animal can be slaughtered or sold. When treatment is performed, practices for bovine mastitis are usually followed. These include intramammary and systemic antibiotics, antiinflammatory agents, and fluid therapy (see section on clinical mastitis treatment). No intramammary or systemic antibiotics are labeled for treatment of mastitis in sheep or goats in the United States, so extralabel drug use is necessary. Beta-

lactam and macrolide antibiotics are often used because of the predominance of staphylococci and (in sheep) *M. haemolytica*.[466] Without efficacy data, it is impossible to make evidence-based recommendations.

Because of the small volume of the ovine and caprine mammary glands, producers often administer one half of the bovine dose when infusing intramammary antibiotics. This is likely to be adequate, provided the pathogen is susceptible, the antibiotic can reach the site of infection, and treatment is continued for a sufficient duration. Depletion of antibiotics from the mammary gland of goats after intramammary infusion is similar to that for cows.[467] However, when using antibiotics labeled for cows, the milk-withholding and slaughter-withholding times should be extended to avoid violative residues.

Economics often drive treatment decisions in small ruminants, but the welfare of the animal must be addressed. Because clinical mastitis in small ruminants is usually caused by gram-positive bacteria, in contrast to the high rate of coliform mastitis in cattle, antibiotics should be administered. Also, analgesics (NSAIDs) are indicated to control pain. Flunixin meglumine administration hastens clinical recovery in both sheep[468] and goats.[469] Neither intramammary nor systemic antibiotics are likely to resolve *Mycoplasma* infection, making euthanasia the most humane option in animals with clinical mycoplasmosis. Euthanasia is also the best option in most cases of gangrenous mastitis; if euthanasia is not performed, it may be necessary to amputate the teat or surgically remove necrotic tissue. Animals with gangrenous mastitis should be segregated to avoid contaminating the environment and transmitting the pathogen (usually *S. aureus*) to herdmates.[470]

36.12.2 Subclinical Mastitis

Subclinical mastitis is more common than clinical mastitis in both sheep and goats. Intramammary infection is identified in 20% to 40% of ewes and does in most surveys.[461,471,472] The prevalence of intramammary infection ranges from less than 10% to more than 90% among sheep flocks[460,473] and less than 10% to more than 60% among goat herds.[461,474] Prevalence increases with parity in goats.[471,475]

Subclinical mastitis is accompanied by reduced milk production and altered milk composition. On dairy farms, this reduces income and adversely impacts the quality of milk and milk products. On farms raising sheep or goats for meat, the weaning weights of nursing animals may be reduced.[476–478]

Coagulase-negative staphylococci (CNS) cause the majority of subclinical mastitis episodes in sheep and goats.[459] Although CNS are considered minor pathogens in dairy cows, this is not the case in small ruminants. Mammary glands infected with CNS, particularly novobiocin-sensitive species, have substantially higher SCC than do uninfected glands.[461,472,474,477] Also, CNS infections in small ruminants usually persist for months. Other subclinical mastitis pathogens of sheep and goats include *S. aureus,* streptococci, enterococci, corynebacteria, and *Mycoplasma* species.[459] Within-herd/flock prevalence of *S. aureus* is typically lower for small ruminants than for dairy cattle.

Subclinical mastitis is most often detected by palpating mammary glands for firmness and abscesses. In meat animals this is done at weaning, breeding, or lambing/kidding. In dairy animals it is done more routinely. Ultrasonograpy can be helpful in detecting abscesses or areas of fibrosis.[479] Although milk culture is the “gold standard” method for diagnosing subclinical intramammary infection, most sheep and goat producers do not routinely culture milk. Indirect diagnostic tests for subclinical mastitis include SCC, CMT, electrical conductivity/impedance, and NAGase activity (see Intramammary Infection and Mastitis). SCC is a more reliable indicator of intramammary infection than CMT,[480] but CMT is more practical. In one trial, electrical

impedance was of no predictive value in sheep and little value in goats.[480] NAGase activity increases with intramammary infection in sheep and goats,[474,481] but more studies are needed to determine the ability of NAGase activity to predict infection accurately.

Somatic cell counts are more likely to be monitored in dairy sheep/goats than meat animals. An SCC threshold of 250,000/mL was suggested for sheep in one report, because 82% of milk samples from uninfected halves had SCC less than 250,000/mL and 91% of samples from infected halves had SCC greater than 250,000/mL.[482] In contrast, the mean SCC for uninfected halves of sheep was 500,000/mL in another study.[480] Thresholds ranging from 500,000/mL to more than 1 million/mL have been recommended for both sheep and goats. The choice of SCC threshold and its value for predicting infection status depend on the prevalence of infection in the flock/herd, as is the case for cattle (see section on mastitis detection). In general, a low SCC is more predictive of a healthy gland than a high SCC of an infected gland.[480,483] SCCs from sequential tests are more valuable than a single test result.

An interesting difference between goats and sheep (or cattle) is that milk secretion in goats is an apocrine process. Anucleated cytoplasmic particles are expelled from the secretory cells into the milk during secretion of milk components. These particles are approximately the same size as somatic cells, average 150,000/mL in goat milk, and they can be mistaken for somatic cells by some counting methods. Therefore, only direct microscopic observation or methods that identify DNA should be used for quantifying somatic cells in goat milk.[484] Another difference between goats and sheep is a higher proportion of neutrophils in normal goat milk. Lastly, the SCC of goat milk increases substantially in late lactation, even in does free of intramammary infection. Counts can exceed 1 million/mL in healthy glands, making SCC an unreliable predictor of intramammary infection in late lactation.[484,485] To explore mastitis prevalence in a goat herd using SCC, goats should be sampled after the postparturient period but before 130 days in milk, to avoid the influence of stage of lactation on SCC.[474]

1139

1140

Geometric mean SCC values for CMT scores of negative, trace, 1, 2, and 3 are 170,000, 309,000, 760,000, 1,911,000, and 8,819,000/mL, respectively, for dairy sheep and 135,000, 148,000, 359,000, 1,110,000, and 7,505,000/mL, respectively, for dairy goats, showing a clear positive relationship between CMT score and SCC.[480] A CMT threshold of 1 is usually recommended for differentiating infected from uninfected halves. However, the CMT has the same drawbacks as SCC, with low scores (negative or trace) being highly predictive of uninfected glands but high scores being poorly predictive (<45%) of infected glands, unless infection prevalence is very high.[480] Bulk tank SCC is useful for estimating the intramammary infection prevalence in dairy sheep and goats,[459] but the proportion of goats in late lactation must be considered when interpreting BTSCC.

Subclinical mastitis in small ruminants is most effectively treated by infusing antibiotics into the mammary glands at dry-off/weaning. Antibiotic products labeled for dairy cows are used. Antibiotic infusion at dry-off/weaning significantly increases cure rate compared with spontaneous cure. Antibiotic infusion at dry-off/weaning also reduces the incidence of new intramammary infections at parturition and the prevalence of intramammary infection throughout lactation, and results in lower SCC and higher milk yield.[481,486,487] There appears to be little difference in efficacy between a full dose of antibiotic and a half dose, so producers typically split one antibiotic tube between two udder halves. When this is done, the cannula should be swabbed with alcohol before inserting it into the second gland.[486] As in cattle, inadequate disinfection of the teat or poor intramammary infusion technique in sheep and goats can lead to opportunistic intramammary infections. Withholding times for milk and meat must be extended and milk tested for antibiotic residues after parturition if

it is to be sold for human consumption. The risk of antibiotic residues by 5 to 7 days after lambing appears to be negligible.[481]

Other mastitis control measures for small ruminants include culling of chronically infected animals, hygienic housing conditions, and good premilking udder hygiene practices. Contagious ecthyma control will reduce the risk of teat lesions and secondary mastitis. Identification and removal of milk-robbing lambs may reduce spread of pathogens from teat to teat. Control measures for contagious mastitis in dairy cows are recommended for dairy sheep and goats; these include postmilking germicidal teat dipping and use of gloves and individual towels when preparing teats for milking. Apparently healthy goats can carry pathogenic *Mycoplasma* species in their external ear canals, often in conjunction with ear mites,[488] but the importance of the ear as reservoir for *Mycoplasma* mastitis is uncertain.[489]

Heritability of SCS in sheep is .10 to .15, with a negative genetic correlation (−0.35 to −0.11) between SCS and milk yield. Genetic selection for mastitis resistance is practiced in certain breeds in some countries.[459] Identification of regions of the ovine genome involved in mastitis resistance has led to use of quantitative trait loci programs for genetic selection in some countries.[459]

36.12.3 Retroviral Mastitis

Retroviral (lentiviral) infections in sheep (ovine progressive pneumonia, maedi-visna)[490] and goats (caprine arthritis-encephalitis)[491,492] can cause interstitial mastitis. Mammary glands become diffusely and homogenously firm, and milk production declines. Viral infection results in an interstitial accumulation of lymphocytes in the mammary gland. The SCC of seropositive (presumptively infected) goats is higher than the SCC of seronegative goats, but not as high as with bacterial intramammary infection.[492] The increase in SCC in seropositive goats may be caused by an increase in mononuclear cells in the milk or a reduction in milk yield. In contrast, retroviral infection in sheep appears to have little effect on SCC.

Retroviral mastitis should be suspected when the udder is firm but not inflamed and the milk appears normal. A positive serologic test result and other signs of retroviral infection (chronic weight loss, increased respiratory effort, arthritis) support the diagnosis. There is no effective treatment for retroviral mastitis, so affected animals must be culled. Feeding colostrum or milk from affected animals to their offspring can transmit the infection.

36.13 MASTITIS IN BEEF CATTLE

Approximately 15% to 40% of beef cows have intramammary infection in one or more mammary glands in most surveys.[493–495] Coagulase-negative staphylococci are the predominant isolates, but *Staphylococcus aureus* is found in 7% to 10% of samples. Streptococci and corynebacteria are isolated occasionally, as are gram-negative bacteria. Milk from infected glands has significantly higher SCC than milk from uninfected glands,[493] but somatic cell counting is not usually performed in beef herds. Clinical mastitis occurs sporadically and is diagnosed and treated as for dairy cows when economically feasible; most mild clinical mastitis cases probably go unrecognized.

The prevalence and etiologic agents of intramammary infection in prepartum beef heifers are similar to those in lactating beef cows.[493,496] In contrast to dairy cattle, clostridia are the predominant bacteria found in the teat canal of beef cattle, followed by *Bacillus* species and staphylococci.[497]

Several modes of mastitis transmission have been proposed for beef cattle. Flies are believed to serve as vectors for staphylococci. This may explain the higher prevalence of intramammary infection in the front glands of beef heifers than the rear glands, because flies on the front glands are less accessible by the tail. Fly-induced scabs on the teats of beef heifers have been shown to harbor staphylococci.[493] Calves may also serve as vectors by transmitting oropharyngeal organisms to the teats or carrying bacteria-laden milk from teat to teat. Unsanitary housing conditions probably increase the risk of infection with environmental pathogens.[498] As with dairy cows, poor udder conformation and teat injuries may predispose to mastitis.

Several studies have demonstrated numeric or significant decreases (up to 40 kg) in weaning weights of calves from beef cows with subclinical mastitis.[493–495] This probably results from reduced milk production. The adverse effect on weaning weight appears to increase with the number of infected glands.[494] In most cases the cost associated with reduced weaning weight is unlikely to justify antibiotic treatment. Selective intramammary antibiotic treatment at weaning based on CMT reaction has been suggested, but CMT score is unlikely to be an accurate predictor of infection. Sanitary housing conditions, appropriate stocking density, and good fly control should help minimize mastitis risk in beef cattle.

1140

1141

36.14 MASTITIS IN HORSES

Mastitis is an uncommon problem in horses, partly because of the small size and inguinal location of the udder, which minimizes exposure to environmental pathogens. Little research has been done on the prevalence of subclinical mastitis in horses, but it is not recognized to be a serious problem. In one study, no pathogens were grown from the milk of 11 mares sampled repeatedly during the first 2 months of lactation, and average SCC was less than 50,000/mL at most sampling times.[499]

Clinical mastitis occurs sporadically in lactating and nonlactating mares; signs range from mild to severe. The most common clinical mastitis pathogen is *Streptococcus zooepidemicus,* but a variety of aerobic bacteria have been isolated from the milk of affected mares.[5,500] In a retrospective study of 28 cases, gram-negative bacteria (coliform bacteria, *Pseudomonas, Actinobacillus, Pasteurella*) were isolated from 42% of milk samples.[5] Streptococci and staphylococci constituted most of the gram-positive isolates. Rarely, mastitis is caused by nonbacterial pathogens. For example, one mare developed unilateral mastitis as a component of disseminated coccidioidomycosis.[501] Verminous mastitis has even been reported.[502]

Clinical signs of mastitis in horses include an enlarged, firm, warm, painful mammary gland and edema of the udder and surrounding tissues. The mare resists milking, and secretions are abnormal in appearance (color, viscosity, consistency). About half of all mares with clinical mastitis are systemically ill, with signs such as fever, tachycardia, tachypnea, anorexia, depression, or agalactia. The mare may be reluctant to move or may adopt an abnormal gait to minimize contact between the hindlimb and the painful gland. Sedation or anesthesia is necessary to achieve a thorough examination of the udder and collection of milk in some horses.[500]

Culturing of the milk is required to identify definitively the causative pathogen of equine mastitis and confirm that antibiotic selection is appropriate. However, bacteria can often be observed on cytologic examination of the milk.[5,503] A differential diagnosis for a firm, enlarged, painful mammary gland is adenocarcinoma, particularly if the udder skin is ulcerated and the secretion is serosanguineous.[504] With adenocarcinoma, neoplastic cells may be seen during cytologic examination of the secretion, or a mammary biopsy may be required. Because bacterial mastitis and adenocarcinoma can occur simultaneously, it is important to reevaluate mares that do not respond as

expected to antibiotic treatment. A differential diagnosis for agalactia in mares is fescue toxicosis. With fescue toxicosis, the udder is not inflamed, and mares may sweat profusely, have prolonged gestation, or give birth to weak or dysmature foals.[505]

Treatment of bacterial mastitis in horses consists of intramammary and systemic antibiotics to combat infection; NSAIDs to reduce pain, inflammation, and fever; and fluids to correct dehydration. Hot packing, hydrotherapy, and frequent stripping of the affected gland are empirically justified supportive measures but may be difficult to accomplish. Furosemide can be administered if edema is substantial.

Broad-spectrum antibiotics should be given until results of cytologic examination or culture of the milk are available. Potentiated sulfonamides, or a combination of penicillin and an aminoglycoside, are reasonable systemic antibiotic choices. Because no antibiotics are labeled for intramammary administration in horses in the United States, intramammary infusion products for cattle are used. Infusion products containing ceftiofur, cephapirin, amoxicillin, or hetacillin are appropriate until the cause of the mastitis is determined. A commercial intramammary infusion product is preferable to a homemade solution because the latter carries a greater risk of unintentional contamination. Intramammary infusion of antibiotics can be difficult to accomplish in horses because of the small size of the teat orifice and the presence of two distinct lobes within each udder half. One or both lobes can be infected, so antibiotics must be directed appropriately. Antibiotic treatment should be continued for at least 5 days to avoid relapse.

The prognosis for survival of horses with bacterial mastitis is good; however, milk production may be transiently or permanently reduced. Fortunately, mastitis is usually unilateral, and recurrence is rare.[5] Most mares respond rapidly to antibiotic treatment. Although spontaneous recovery is possible, it is unethical to withhold treatment from a mare that is ill or in discomfort. The prognosis for mammary adenocarcinoma is poor, even with surgical removal of the affected mammary gland(s) and local lymph nodes, because of the high rate of metastasis.[504]

36.15 MASTITIS IN SOUTH AMERICAN CAMELIDS

As with the horse, the udder of South American camelids (SACs) is nonpendulous, has small teats, and is protected from trauma and environmental contamination by its caudal location. Because they are not reared for milk production, SACs are spared the contagious mastitis risks associated with hand or machine milking. Therefore, it is not surprising that the prevalence of mastitis is low. In a survey of 100 llamas, potential mastitis pathogens were isolated from 21% of mammary glands, with 57% of llamas having at least one infected gland; the majority of isolates were coagulase-negative staphylococci.[506] However, isolation of an organism was not associated with an increase in SCC, CMT score, NAGase activity, or pH, which indicates that the organisms were not causing mastitis. None of the llamas exhibited signs of clinical mastitis, and 88% had a CMT score of 0 (negative). The SCC (direct microscopic count) was 300,000/mL or less in all cases. Therefore, CMT and SCC scores for healthy llamas are much lower than for healthy sheep and goats. Low SCC values were also found when milk from 10 llamas was tested weekly for the first 27 weeks of lactation.[507] The NAGase activity and lactoferrin concentration in llama milk is higher than in sheep or cow milk, which may help protect against infection.[508]

Despite a low prevalence of subclinical mastitis, llamas occasionally experience episodes of acute clinical mastitis,[509] most often after birthing. Treatment includes systemic and local antibiotics and antiinflammatory agents. As with the horse, intramammary antibiotic infusion is complicated by the presence of two distinct lobes per mammary gland. Because each lobe has its own teat canal and orifice, both orifices should be cannulated when infusing intramammary antibiotics. The orifices are usually too small to accommodate the cannulas on

intramammary infusion products for cattle; therefore a 3.5 French tomcat catheter is recommended.[4] As with other species, disinfection of the teat end and aseptic infusion techniques are essential to prevent iatrogenic infection. Broad-spectrum antibiotics should be administered until culture results are available, because both gram-positive and gram-negative bacteria have been isolated from mastitic llamas. Systemic antibiotics should be used in conjunction with intramammary antibiotics in llamas that are systemically ill. Pain should be addressed by administering NSAIDs, with fluids administered if needed. Hot packing and frequent stripping of the affected gland are empirically justified treatments that may prove difficult because many llamas resist handling of the udder. Prognosis for survival is good if mastitis is treated early, but milk production may be reduced.

1141

1142

36.16 UDDER EDEMA

Dairy cattle frequently develop physiologic edema of the udder during the periparturient period. Other large animals are affected less frequently. Physiologic udder edema must be differentiated from *pathologic* edema, which can accompany mastitis and diseases of other body systems. *Physiologic* udder edema is symmetric, is cool to the touch, and pits on palpation. It can be limited to the udder or extend cranially along the ventrum or into the perineal region. In contrast, the edema that accompanies mastitis is more focal, is asymmetric, and is accompanied by abnormal milk and an inflamed mammary gland. Intermandibular and brisket edema, which are often observed in cows with congestive heart failure or severe hypoproteinemia, do not occur in cows with physiologic udder edema.

In most cases, physiologic edema is of little consequence and resolves spontaneously after parturition. However, treatment is recommended if the udder becomes excessively large and heavy, because this threatens the integrity of the udder suspensory apparatus and predisposes to teat injury and mastitis. Severe edema also can hinder ambulation or impair milking or nursing of the teats. If the edematous udder impinges on the skin of the thigh, moist dermatitis and secondary infection may develop, and the skin may slough; this condition is referred to as *udder scald*.

The mechanism(s) of physiologic udder edema is uncertain. Supplementing the ration of prepartum dairy cows with high concentrations of sodium or potassium salts significantly increases the incidence and severity of edema.[510] However, serum biochemical values and fractional clearance of electrolytes are similar in affected and nonaffected cows.[511] Increased capillary hydrostatic pressure (resulting from changes in mammary blood flow and intramammary pressure that occur around parturition) might be involved, as might incompetent valves in the cranial superficial epigastric veins draining the udder. Cows with udder edema have higher blood pressure in the cranial superficial epigastric veins than do unaffected cows, and blood pressure is inversely related to mammary blood flow.[512] Poor udder suspension can also predispose to physiologic udder edema.

First-calf heifers and high-producing cows are at greatest risk of developing udder edema. Other risk factors are not well documented. In a case-control study of heifers in Florida, the risk of udder edema increased as height of the heifer increased, was higher if calving occurred in winter than in summer, and was higher if the fetus was male rather than female.[513] Heifers with udder edema in the first lactation were more likely than unaffected heifers to develop edema in subsequent lactations.[513]

Treatment of udder edema includes preventing excessive salt intake and administering a diuretic. In the United States, furosemide is labeled for use in dairy cows, has 48-hour milk-withholding and slaughter-withholding times, and is the diuretic of choice for treating udder edema. In one study, high cranial superficial epigastric venous pressure in cows with udder edema was reduced by IV administration of furosemide (500 mg), but not hydrochlorothiazide (250 mg) or acetazolamide (500 mg).[512] Repeated administration of furosemide for several

days should be avoided, but if repeated dosing is necessary, cows should be monitored for signs of electrolyte imbalance. Although corticosteroids have been recommended for treatment of udder edema, their efficacy is questionable. Prepartum milking reduces the severity of edema[514] but also decreases colostral immunoglobulin concentration at calving, so an alternative source of colostrum is needed. Increased milking frequency, udder massage, exercise, and hydrotherapy are empirically justified treatments for udder edema. Udder supports are available for cows with excessively pendulous or heavy udders.

36.17 BLOODY MILK

It is not uncommon to observe blood in postpartum mammary secretions. Small vessels may rupture as a result of trauma or in conjunction with udder edema. The milk is usually light pink to red or brown and may contain blood clots. Antibiotic treatment is not indicated. Bloody milk can also accompany severe clinical mastitis or gangrenous mastitis, both of which have a poor prognosis, but physical examination of the animal will identify these conditions.

Bloody milk should be withheld from sale for human consumption. The milk usually returns to normal appearance within 1 week. However, because blood contains natural antimicrobial inhibitors, bloody milk may cause false-positive antibiotic residue test results. The IgG_1 concentration of bloody colostrum is similar to that of normal-appearing colostrum, meaning it is not necessary to discard colostrum simply because it contains blood.[65]

36.18 COLOSTROGENESIS AND COLOSTRAL IMMUNOGLOBULIN TRANSPORT

About 2 weeks before parturition, the mammary gland begins producing colostrum, a process that accelerates as parturition approaches. Colostrum contains an appropriate balance of nutrients for the neonate, as well as substances that provide protection against infection and modulate development of the immune system.[515,516] Of particular importance are colostral immunoglobulins, which are derived predominantly from maternal serum, by selective transport across mammary epithelial cells.[517,518]

In cattle, all immunoglobulin (Ig) isotypes are transported into colostrum,[519] but IgG transport predominates. Mammary epithelial cells express receptors for both IgG_1 and IgG_2 during the periparturient period, but IgG_1 receptors are more abundant and of higher affinity.[518] Preferential transport of IgG_1 results in an IgG_1/IgG_2 ratio of at least 7:1 in colostrum, compared with 1:1 in plasma.[517] The IgG_1 concentration of Holstein colostrum averages 40 to 80 g/L, with substantial variability among cows.[520]

Immunoglobulin G_1 is also the most abundant Ig in the colostrum of sheep and goats, with concentrations averaging 60 to 80 g/L in sheep[521,522] and 40 to 60 g/L in goats.[523] Preferential transport of IgG_1 over IgG_2 has been demonstrated.[523,524] Less is known about colostral Ig isotypes and transport in SACs,[525,526] but mean colostral IgG concentration for llamas and alpacas in one report was 193 g/L,[525] much higher than for small ruminants.

Equine colostrum contains IgGa, IgGb, IgGc, IgG(T), and IgA, but IgGb predominates, as is true for serum. In one study, serum-to-colostrum concentration ratios of these five isotypes were 0.06, 0.12, 0.16, 0.17, and 0.18, respectively, demonstrating that all are greatly increased in colostrum.[527] Total IgG in equine colostrum is highly

variable, with concentrations ranging from less than 10 to almost 400 g/L.[527,528] In contrast to colostrum, IgA is the predominant Ig in equine milk.[527]

Neonatal ruminants are agammaglobulinemic at birth and rely on absorption of colostral IgG_1 across the intestinal epithelium during the first day of life to achieve protective circulating Ig concentrations.[522,529] Foals are also dependent on intestinal absorption of colostral Ig, particularly IgGb.[527] Most dairy calves are hand-fed a fixed volume of colostrum by bottle, bucket, or esophageal feeder.[530] Therefore, the IgG_1 concentration of the colostrum is critical in determining if a sufficient mass (≥125 g/calf) of IgG_1 is fed. Beef calves, small ruminant neonates, and foals usually obtain colostrum by suckling the dam, so both the amount of colostrum suckled and its Ig concentration are critical in determining if a sufficient mass of Ig is ingested.

A number of factors influence colostral IgG concentration. Colostral IgG concentration is typically lower for cows in first or second lactation than cows in third or greater lactation.[65,530] In contrast, colostral IgG concentration was highest in 3- to 10-year-old mares and lower in older mares in one study.[528] In sheep, yearlings had higher colostral IgG_1 concentrations than older ewes.[521] Beef cows typically produce colostrum of higher IgG concentration than dairy cows,[531] and breed differences in colostral IgG concentration are apparent in both ruminants and horses.[521,528,532,533]

Differences in colostral IgG concentrations among species, or among animals within a species, probably result largely from the volume of colostrum produced. Colostral IgG concentration is negatively correlated with colostral volume in dairy cows, meaning that colostrum from high-yielding cows frequently has lower IgG concentration than colostrum from lower yielding cows.[65,530]

Colostral IgG concentration is highest at the first milking after parturition and declines rapidly thereafter, which means that a delay in time to first milking results in a progressive reduction in IgG concentration.[534] The decline in colostral IgG concentration in horses appears to be even more rapid than in cattle.[527] Intramammary infection reduces colostral yield in dairy cows but not colostral IgG concentration.[535]

Direct measurement of IgG concentration in colostrum is time-consuming and costly, so IgG concentration is often estimated from the specific gravity of the colostrum. In cattle, specific gravity is positively correlated with colostral protein concentration and, to a lesser extent, IgG_1 concentration[520,532,536]; the relationship between specific gravity and IgG_1 may differ among breeds of cows.[532] In horses, there is also a positive correlation between colostral specific gravity and IgG concentration.[528] Cattle producers frequently measure colostral specific gravity on-farm, using a commercial colostrometer. Values marked on the colostrometer do not accurately reflect actual IgG_1 concentration,[536] but the colostrometer can be used as a tool to differentiate very poor colostrum from excellent colostrum. Unfortunately, the appearance of bovine colostrum is not indicative of its IgG concentration.[65]

Transfer of colostral Ig to the neonate is discussed in Section Three of this book.

37 Chapter 37 Diseases of the Hematopoietic and Hemolymphatic Systems

Monica Aleman

Gary P. Carlson

37.1 DISEASES ASSOCIATED WITH BLOOD LOSS OR HEMOSTATIC DYSFUNCTION

DEBRA DEEM MORRIS

Blood loss may be acute or chronic, and the clinical and laboratory manifestations differ widely because physiologic adaptation occurs in the chronic state.

37.2 ACUTE BLOOD LOSS

Common causes for acute blood loss include trauma (e.g., severe lacerations), surgical procedures (e.g., dehorning, castration), and erosion of the carotid artery by guttural pouch mycosis in horses. External hemorrhage is immediately obvious, but hemorrhage into a major body cavity may be occult (e.g., spontaneous rupture of middle uterine artery; splenic rupture resulting from trauma or erosion of major vessel by abscess, aneurysm, or neoplasia). Hemoperitoneum may induce signs of colic, and hemothorax is generally attended by dyspnea. Acute massive blood loss induces hypovolemic shock characterized by tachycardia, tachypnea, cold extremities, pale mucous membranes, muscle weakness, and eventual death resulting from cardiovascular collapse.

Acute blood loss does not initially cause a change in the packed cell volume (PCV) or total plasma protein (TPP), although rapid mobilization of extracellular fluid to maintain circulating blood volume causes the PCV and TPP to decline within 12 to 24 hours. The severity of blood loss may be partially masked by splenic contraction because shock causes activation of the sympathetic nervous system. Icterus is absent, and bone marrow erythroid hyperplasia is delayed by 3 to 4 days. Peripheral signs of erythroid regeneration in horses are limited to mild anisocytosis with a variable increase in mean corpuscular volume. Ruminants show erythrocyte polychromasia, basophilic stippling, Howell-Jolly bodies, and occasionally, nucleated erythrocytes within 4 days of the onset of hemorrhage.

37.2.1 Diagnosis

Diagnosis of acute blood loss is based on clinical signs, evidence of recent hemorrhage, and anemia accompanied by hypoproteinemia. Hemoperitoneum and hemothorax may be suggested by ultrasound and by abdominocentesis and thoracocentesis, respectively.

37.2.2 Treatment

Treatment of acute blood loss should initially be aimed at stopping the hemorrhage. External hemorrhage may be managed by pressure wraps or appropriately placed ligatures; however, it may be inadvisable to attempt to control internal hemorrhage when the patient is a poor risk for general anesthesia and the source of hemorrhage may not be found. Hypovolemic shock should be treated by prompt intravenous (IV) administration of 40 to 80 mL/kg body weight of sodium-containing crystalloid solutions. Studies indicate that a small volume of hypertonic saline (4 to 6 mL/kg of 7.2% sodium chloride) may temporarily reverse the pathophysiologic

sequelae of severe hemorrhagic shock.[1,2] The total volume of necessary crystalloid solution is usually much greater than the volume of blood lost because crystalloid solutions distribute throughout the extracellular space. The clinical response to fluid administration should be evaluated in light of ongoing losses to determine the necessary replacement volume.

If anemia becomes life threatening, whole-blood transfusion must be considered. A PCV less than 20% in an animal with acute blood loss suggests depletion of erythrocyte reserves, and persistent reduction of the PCV to 12% or less over 24 to 48 hours indicates the need for blood transfusion. A low but stable PCV (12% to 20%) does not necessitate transfusion because transfusion should be reserved for cases in which oxygen delivery to the tissues is inadequate to support life. Blood transfusion can only be viewed as a temporary therapeutic procedure because even crossmatch-compatible, allogeneic erythrocytes are removed from the circulation by the mononuclear phagocyte system within 2 to 4 days of transfusion.[3] Horses and cattle display a high degree of blood type polymorphism, and minor antigenic incompatibilities are only delineated by blood typing.[4] Serum antibodies against nonhost erythrocyte antigens (erythrocyte alloantibodies) probably mediate the short lifespan of transfused erythrocytes. Compatibility testing is used to avert life-threatening antigen-antibody reactions caused by major blood group mismatching.

The routine crossmatch involves incubating washed erythrocytes from donor (major) and recipient (minor) with serum from the other. Gross and microscopic examination for clumping demonstrates serum agglutinins in horses. Sensitized cattle erythrocytes do not become clumped in saline solution but do lyse in the presence of rabbit complement, so only a hemolytic crossmatch can be performed in this species. Not all equine erythrocyte alloantibodies act as agglutinins, and hemolysins must be detected by adding complement to the reaction mixture. Pooled rabbit serum must first be absorbed with equine erythrocytes to remove naturally occurring antibodies. The need for special handling and storage of rabbit serum makes hemolytic crossmatch procedures impractical for most veterinarians. These tests are best performed by veterinary hematology laboratories (e.g., Veterinary Genetics Laboratory, School of Veterinary Medicine, University of California, Davis), which usually require serum and whole blood in sodium citrate or acid-citrate-dextrose (ACD) to crossmatch.

1144

1145

The first transfusion of whole blood to a horse or ruminant that has not been previously transfused or sensitized by immunization or pregnancy is usually well tolerated because natural alloantibodies are of low concentration and weak activity. After incompatible transfusions, alloantibodies develop rapidly, making subsequent transfusions more hazardous.

Blood for transfusion should be collected aseptically into sterile containers containing sodium citrate (2.5% to 4%) or ACD solution and used immediately. The necessary dosage can only be estimated, but in most cases, replacing 20% to 40% of the calculated blood loss is sufficient to maintain life until the bone marrow can respond. A drop in PCV from 36% to 12% in a 500-kg animal (8% body weight blood) represents a loss of 27 L of blood. In this case, 6 to 8 L of whole blood would be therapeutic and easily donated by another 500-kg individual. Blood warmed to 37° C (98.6° F) should be administered through an in-line filter to remove clots. After pretransfusion vital parameters have been recorded, 0.1 mL blood/kg body weight is given over 5 to 10 minutes and the evaluation repeated. If parameters and attitude are unchanged, the transfusion can be continued at a rate not to exceed 20 mL/kg/hr. The recipient should be continuously monitored so that the transfusion can be stopped if adverse reactions occur, such as tachypnea, dyspnea, restlessness, defecation, tachycardia, piloerection, muscle fasciculations, or sudden collapse. Although these signs may not indicate anaphylaxis, severe reactions should be treated with epinephrine (0.01 to 0.02 mL/kg, 1:1000). Mild signs may respond to a slowed transfusion rate or administration of corticosteroids or flunixin meglumine. Because it is often not possible to delineate the cause of transfusion reactions, the safest approach is to discontinue the blood and administer isotonic crystalloid solutions.

The prognosis is good for most cases of acute blood loss if hypovolemic shock is quickly treated and the bleeding stops. The normal bone marrow begins to replace lost cells within 5 days. Sequential analysis of the PCV will be necessary to determine whether blood loss is controlled. Examples of specific disorders follow.

37.2.3 Guttural Pouch Mycosis

See Chapter 31.

37.2.4 Hemoperitoneum in Horses

MONICA ALEMAN

Hemoperitoneum is the accumulation of blood in the abdominal cavity, which can be a life-threatening problem. Causes associated with hemoperitoneum in the horse include trauma, postoperative abdominal hemorrhage, neoplasia, complications from pregnancy and foaling (uteroovarian, middle uterine, and external iliac artery rupture), organ rupture, mesenteric injury, coagulopathies, ovarian hematoma, systemic amyloidosis, and idiopathic causes.[5–11] The underlying cause of hemoperitoneum may be identified in the majority of the cases (78%).[11] Trauma (mainly of spleen, as well as reproductive tract with associated vessels in mares) and neoplasia are the most common causes of hemoperitoneum.[7,11]

A recent retrospective study of 67 horses with hemoperitoneum revealed that thoroughbreds and Arabians were overrepresented breeds.[11] In addition, middle-aged and older horses (>13 years old) were also overrepresented. Females may be overrepresented.[10,11] The most clinical signs include abdominal discomfort, lethargy, hypovolemic shock, pale mucous membranes, prolonged capillary refill time, tachycardia, and tachypnea.[10,11] Other clinical signs are anorexia, reluctance to move, weakness, trembling, cool extremities, and abdominal distention.[10]

Clinicopathologic abnormalities include anemia, neutrophilia, lymphopenia, thrombocytopenia, hypoproteinemia, hypocalcemia, and azotemia.[10] Abnormalities in clotting parameters may be observed, depending on the cause. Hemorrhagic abdominal effusion is characterized by high red blood cell (RBC) count (>2.4 million RBCs/μL), PCV (≥18%), and total protein (≥3.2 g/dL), with a normal to high leukocyte count.[10] Central venous pressure and blood lactate concentration appear to be early indicators of hypovolemia caused by acute blood loss.[12] Swirling fluid and the site of hemorrhage may be evident on abdominal ultrasound.

Primary goals of therapy consist of treating hypovolemic shock, restoring perfusion and oxygen delivery to tissues, correcting fluid deficits, stopping further blood loss, and preventing complications. Blood transfusion should be considered if anemia becomes life threatening. The use of antifibrinolytic and procoagulant agents have been reported in the literature, but controlled studies on its efficacy and safety in the horse with acute blood loss are lacking. Physical activity must be restricted in affected patients.

The short-term outcome is strongly associated with the underlying cause.[11] Horses with neoplasia, uterine artery rupture, mesenteric injury, or disseminated intravascular coagulation (DIC) are a greater risk of death. The survival rate has been reported to range from 51% to 74%.[10,11] Poor short-term outcome was significantly associated with high respiratory rate in one study.[11] Prepartum hemorrhage appears to be associated with a poorer prognosis than postpartum hemorrhage (100% vs. 20% mortality, respectively).[11]

37.2.5 Hemothorax

Hemothorax may occur secondary to trauma (including lung biopsy), neoplasia, and strenuous exercise[13] (see Chapter 31). Hemothorax in neonatal foals may be the result of lacerated lungs and vessels from fractured ribs[14] (see Chapter 19).

37.2.6 Exercise-Induced Pulmonary Hemorrhage

Exercise-induced pulmonary hemorrhage (EIPH) has not been associated as a major cause of blood loss. EIPH is associated with high intensity exercise in horses. An estimated 14% to 75% of racehorses examined by endoscopy have EIPH.[15] Based on bronchoalveolar lavage analysis, a study suggested that 100% of horses performing strenuous exercise have EIPH.[16] EIPH has been reported in various breeds. A recent study reported that the frequency of EIPH is associated with race type, distance, gender, and age. In one study, epistaxis was more common in females, in older horses than in horses less than 2 years old, after steeplechase races than flat races, and with shorter distances (≤1600 m [1 mile] long).[17] Recurrence rate in that study was reported to be 4.64%. The pathophysiology of EIPH is not completely known. For a complete description of this disorder, see Chapter 31.

37.3 CHRONIC BLOOD LOSS

DEBRA DEEM MORRIS

A number of diseases can result in chronic loss of blood that is insidious until clinical signs of anemia develop. Physiologic adaptation to gradually developing tissue hypoxia generally masks signs of anemia until the PCV is less than 15%. Causes for chronic blood loss include bleeding gastrointestinal (GI) lesions, certain renal diseases, hemostatic dysfunction, bloodsucking external parasites, and haemonchosis (especially in goats and sheep). 1145 1146

Gastrointestinal hemorrhage is usually caused by neoplasia (especially gastric squamous cell carcinoma in horses and abomasal lymphoma in cattle), parasitism, or mucosal ulceration (e.g., abomasal ulcers in cattle, nonsteroidal antiinflammatory drug [NSAID] toxicity in horses). Significant hemorrhage may occur in ruminants heavily infested with *Haemonchus contortus* shortly after they are treated with an anthelmintic. Generally, GI hemorrhage is best detected by chemical determination of fecal occult blood because melena rarely occurs in horses, and bleeding abomasal ulcers cannot be excluded in cattle when melena is absent. Because of the low specificity of tests for fecal occult blood, the diagnosis of chronic GI blood loss is usually supported by strong clinical suspicion and ruling out other sources of hemorrhage.

Although renal papillary necrosis (caused by NSAID therapy) and urinary calculi cause hematuria, anemia rarely results. Renal neoplasia or congenital renal vascular anomalies rarely may be associated with chronic blood loss anemia. Other causes of blood loss include idiopathic hematuria and idiopathic recurrent hematuria of Arabian horses.

Disorders of hemostasis may cause internal or external hemorrhage that leads to anemia if enough blood is lost. Qualitative or quantitative abnormalities of blood vessels, platelets, or coagulation factors result in hemostatic dysfunction (see next section). Loss of erythrocyte iron secondary to chronic severe blood loss may result in iron deficiency anemia. Hypoferremia or reduced serum ferritin develops with increased total iron-binding capacity and reduction in marrow iron.

The aim in management of chronic blood loss is to determine the primary cause. Treatment of the anemia itself is rarely indicated. Iron deficiency may be alleviated by oral supplementation with ferrous sulfate, although good-quality forages contain more than adequate amounts of iron. Parenteral iron supplementation as iron dextran should be avoided because it has been associated with anaphylactoid reactions in large animals. Examples of specific disorders follow.

37.3.1 Gastric Ulceration

MONICA ALEMAN

Gastric ulceration in horses is also known as *equine gastric ulceration syndrome* (EGUS). Although EGUS is not an important cause of blood loss, it has a high prevalence among adult horses. Thoroughbred racehorses have the greatest prevalence (82% to 93%), followed by endurance horses (67%), show horses (58%), hospitalized horses (49%), and geriatric patients with abdominal pain (18%).[18–22] Gastric ulcers were found in 66.6% of pregnant and 75.9% of nonpregnant mares in a thoroughbred breeding farm.[23] Clinical signs may include poor hair coat, decreased appetite, poor performance, nervous disposition, abdominal pain, teeth grinding, and salivation. Proposed causes of gastric ulceration include exercise, transportation, grazing deprivation, alternating periods of feeding and fasting, diets with high concentrate content, and confinement. For a complete description of gastric ulceration, see Chapter 32.

37.3.2 Right Dorsal Colitis

Right dorsal colitis (RDC) is an enteropathy associated with administration of NSAIDs, most often phenylbutazone.[24,25] Other proposed factors that predispose to RDC include infection, immune-mediated response, genetics, and stress. The pathogenesis of RDC is unknown. NSAIDs act by inhibiting cyclooxygenase (more inhibition of constitutively expressed COX-1 than inducible expressed COX-2 during states of inflammation), which will cause inhibition of the production of prostaglandin E resulting in hypoxic or ischemic GI mucosal damage and may delay mucosal healing.[25]

Ponies and young performance horses appear to be predisposed to RDC. The clinical signs include inappetence, lethargy, intermittent or episodic colic, diarrhea, and weight loss.

Clinicopathologic abnormalities may include mild anemia, moderate to severe hypoproteinemia with hypoalbuminemia, hypocalcemia, and in some cases azotemia. Although mild anemia may be seen in most cases, horses occasionally present with severe anemia and hematochezia. RDC often develops over days or weeks. (See Chapter 32.)

37.4 HEMOSTATIC DYSFUNCTION

DEBRA DEEM MORRIS

37.4.1 Basic Physiology of Normal Hemostasis

Understanding the pathogenesis and manifestations of hemostatic disorders is based on knowledge of the normal physiologic mechanism of hemostasis. Hemostasis can be viewed as two interrelated components,

coagulation and fibrinolysis (both with their respective inhibitors), which function to stop bleeding from a damaged blood vessel and maintain nutrient blood flow.

Coagulation is mediated by blood vessels, platelets, and blood procoagulant proteins. When a blood vessel is damaged, vasoconstriction occurs, followed by rapid adherence of platelets to subendothelial collagen. Platelet adhesion causes membrane conformational changes that trigger aggregation, contraction, and granule secretion (the basic platelet reaction). Platelet phospholipoprotein (platelet factor 3) provides the necessary surface to catalyze interactions among the activated coagulation proteins that result in thrombin formation. Coagulant proteins are localized to this hemostatic plug because the platelet surface protects them from plasma anticoagulants. Through an incompletely understood mechanism, platelets also prevent spontaneous hemorrhage into the skin and mucous membranes by maintaining "vascular integrity."

Procoagulant proteins circulate in the blood as precursive forms *(zymogens)* that must be altered during coagulation to become active. Numerous communications exist between the traditional extrinsic and intrinsic pathways, although initiating mechanisms remain distinct.[26] The extrinsic system is initiated when lipoprotein *tissue factor* (TF) gains access to the bloodstream. TF is widely distributed in most tissues, including endothelial cells and monocytes, and may be increased or secreted in response to numerous pathologic stimuli, such as bacterial endotoxin. Intrinsic coagulation is initiated when blood is exposed to a negatively charged surface such as activated platelets. Because of reciprocal activation between factor XII and prekallikrein, the intrinsic coagulation pathway stimulates formation of numerous inflammatory mediators (e.g., kinins, complement). Both coagulation pathways culminate in the formation of activated factor X (Xa), by which thrombin is generated. In addition to catalyzing the conversion of fibrinogen to fibrin, *thrombin* promotes platelet aggregation, enhances cofactor activities of factors V and VIII, and activates factor XIII and protein C.[27] Mechanisms to localize coagulation to the site of vascular injury are critical to protect against generalized thrombosis.[28] Plasma anticoagulant proteins include the serpins, which inhibit activated coagulation factors, and the protein C system, which is directed against cofactors V and VIII.[29] *Antithrombin III* (AT III), the main physiologic inhibitor of thrombin and Xa, normally provides 70% of the anticoagulant activity of plasma. Although not absolutely needed, heparin accelerates AT III action by 2000-fold.[30] Activated protein C destroys factors V and VIII, ultimately limiting its own activation, which depends on thrombin and endothelial cofactor, thrombomodulin. Protein S enhances the anticoagulant ability of protein C.

1146

1147

The *fibrinolytic system* is activated simultaneously with coagulation and functions to prevent tissue ischemia by limiting the extent of fibrin clot formation. Plasmin, primarily responsible for degradation of fibrin, exists in the plasma as the zymogen *plasminogen*. Plasminogen has a high affinity for fibrin, as does *tissue plasminogen activator* (tPA); therefore, clots contain the necessary components to allow lysis from within, and systemic plasmin formation is avoided. *Alpha-2-antiplasmin* (α_2-AP), the main physiologic inhibitor of plasmin, competes with the binding of plasminogen to fibrin, and the clot contains equal amounts of both glycoproteins. Because of this molar balance between α_2-AP and plasminogen, a normal blood clot does not lyse spontaneously, despite fixation of tPA. Physiologic inhibitors of tPA (PAIs) are found in plasma, platelets, and endothelial cells, and platelet-derived PAI also protects a blood clot against premature lysis. Clot lysis is initiated if additional tPA is taken up from the surrounding tissues; stasis upstream from the occluded vessel is a potent stimulus for release of endothelial tPA. Conversion of plasminogen to plasmin allows partial digestion of fibrin and exposure of additional plasminogen-binding sites. When this additional plasminogen is converted to plasmin, the inhibitory effect of α_2-AP is overcome, and clot lysis is accelerated. Plasmin hydrolyzes fibrinogen and fibrin with equal affinity, as well as numerous other procoagulants, and it can activate complement and kininogen. The physiologic actions of plasmin are limited to the fibrin clot by the affinity between the latter and plasminogen and the presence of α_2-AP in blood. Because of multiple interactions between the coagulation and

fibrinolytic systems, the most important factor that determines the rate of fibrinolysis is the rate of fibrin formation.[31]

37.4.2 Inherited Coagulation Disorders

Inherited deficiencies of factors VIII,[32] IX, XI,[33] and prekallikrein[34] have been described in horses. Holstein cattle may have inherent factor XI deficiency.[35] Congenital factor VIII deficiency (hemophilia A) is sex linked and recessive, occurring only in males. Factor XI deficiency in cattle is transmitted as an autosomal recessive trait.[35] The inheritance pattern of the other deficiencies has not been proved.

Clinical signs of clotting factor deficiency reflect the tendency for abnormal hemorrhage from larger vessels (e.g., subcutaneous hematomas; hemarthroses; epistaxis; melena; hematuria; prolonged bleeding after trauma, diagnostic procedures, or surgery). Petechiae are a feature of vascular or platelet disorders and are not caused by clotting factor deficiency. Clinical signs do not always result from inherited clotting factor deficiencies. Cattle deficient for factor XI and horses with prekallikrein deficiency have complete in vivo coagulation competency. Prekallikrein appears to perform an accelerating rather than required role in activation of factor XII.[26] Activated factor XII activates factor XI, which then catalyzes the remainder of the clotting sequence. Factor XII is also capable of activating factor VII in the extrinsic pathway,[26] which may explain why factor XI deficiency does not cause a hemorrhagic diathesis. Values for the coagulant part of factor VIII (VIII:C) or factor IX must be reduced to less than 5% of normal before spontaneous hemorrhage occurs. Less severe deficiencies may result in excessive hemorrhage only after trauma.

The major differential diagnoses for heritable factor deficiencies include the acquired coagulation factor—deficient states, DIC, warfarin toxicosis (horses), moldy sweet clover toxicosis, and acute hepatic disease. The heritable clotting factor deficiencies involve proteins in the intrinsic pathway; thus a prolonged activated partial thromboplastin time (aPTT) is the only hemostatic abnormality. Acquired coagulation factor deficiencies involve proteins in the extrinsic or common pathways as well, causing a trend toward prolongation of both the prothrombin time (PT) and aPTT. The definitive diagnosis of heritable clotting factor deficiency must be based on specific quantitative assays of intrinsic clotting factors. The only possible treatment for heritable clotting factor deficiency is replacement of clotting factors through the administration of fresh plasma. Specific clotting factor concentrates are not commercially available for large animals, and the rarity of specific factor-deficiency states that produce clinical signs makes the development of these products unlikely. Because of the expense of therapy and the potential for complications, the long-term prognosis for horses with hemophilia A or multiple congenital coagulation factor defects is poor. Cattle with factor XI deficiency apparently live a normal life but may be more susceptible to secondary diseases.[35]

37.4.3 Thrombasthenia in Horses

MONICA ALEMAN

37.4.3.1 GLANZMANN'S THROMBASTHENIA

Glanzmann's thrombasthenia (GT) is a rare inherited platelet defect caused by quantitative or qualitative change in the platelet glycoprotein complex IIb-IIIa (integrin $\alpha_{IIb}\beta_3$). These subunits are encoded by separate genes, and in order to form a stable functional complex on the platelet surface, both subunits must be expressed. This complex was recognized as the receptor that mediated platelet aggregation and was termed

the *fibrinogen receptor*. GT has been documented in humans and dogs.[36,37] Clinical signs in these species include purpura, epistaxis, and gingival bleeding. There have been four reports of thrombasthenia in the horse, two of which (4-year-old quarter horse, 7-year-old cross-thoroughbred gelding) were confirmed with various tests, including genetic analysis.[38–41] The prominent clinical sign is chronic, intermittent epistaxis unrelated to exercise. Other signs include petechial and ecchymotic hemorrhages in the nasopharynx.

Mild anemia may be observed. Platelet count, activated coagulation time, PTT, PT, thrombin time (TT), fibrin degradation products (FDPs), and plasma concentrations of von Willebrand (vW) factor antigen are normal. However, gingival bleeding time is prolonged (>60 minutes, control horses <2 minutes), clot retraction test is greatly reduced, and platelet aggregation in response to various agonists (as measured by aggregometry) is greatly impaired. Platelet morphology is normal on electron microscopy. Flow cytometric studies using CD41/CD61 monoclonal antibodies have revealed a reduction in the $\alpha_{IIb}\beta_3$ integrin on platelet surfaces.[40] These findings are the basis for the diagnosis of GT.

Christopherson et al.[41] found a single nucleotide change in codon 41 in exon 2 of the gene encoding integrin α_{IIb} in two affected horses. This mutation would encode a proline instead of an arginine, which would result in an aberrant conformation that would prevent association of α_{IIb} with integrin β_3 with ultimate lack of expression of the complex on platelet surface. Currently, treatment is not available.

1147

1148

37.4.3.2

HERITABLE BLEEDING DIATHESIS (OTHER THAN GLANZMANN'S THROMBASTHENIA)

Severe bleeding diathesis was reported in a 2-year-old thoroughbred filly presented for prolonged bleeding time after minor insults.[42] The filly's template bleeding time was longer than 120 minutes, versus 5.5 minutes in control horses.[42] Platelet concentration, PT, PTT, antithrombin III, and coagulation factors (vW, VIII, IX, XI, XII) were unremarkable. Platelet-rich plasma (PRP) aggregated normally in response to a range of agonists (adenosine diphosphate, thromboxane A_2) but was slightly prolonged in response to thrombin and collagen.[43] Several integral platelet membrane glycoproteins involved in aggregation and clotting (e.g., GPIb, GPVI, $\alpha_{IIb}\beta_3$) were present in this filly. However, this filly had a reduced prothrombinase activity, production of thrombin, and binding of fibrinogen.[43] The mare's disorder results in decreased platelet aggregation and ineffective clotting. Offspring of the affected mare were also affected.

37.4.4

Acquired Hemostatic Disorders*

MONICA ALEMAN (MA)

DEBRA DEEM MORRIS (DDM)

JOHN E. MADIGAN (JEM)

Acquired defects of hemostasis may be divided into those involving blood vessels, platelets, and coagulation factors, although some diseases affect more than one component.

37.4.4.1

VASCULITIS

Vasculitis is a clinicopathologic process that involves inflammation and necrosis of blood vessel walls, regardless of size, location, or cause.[44] Vasculitis in large animals is generally a secondary manifestation of a primary infectious, toxic, or neoplastic disorder and has characteristics of hypersensitivity vasculitis in humans. The predominant involvement of small vessels in the skin (e.g., venules, arterioles) is the hallmark of hypersensitivity vasculitis.

The clinical manifestations of vasculitis include demarcated areas of dermal or subcutaneous edema, which may progress to skin infarction, necrosis, and exudation.[45] Hyperemia, petechial and ecchymotic hemorrhages, and ulceration of mucous membranes are common. Although the skin and mucous membranes are predominantly involved, hemorrhage and necrosis may occur in any organ system, resulting in conditions such as lameness, colic, dyspnea, and ataxia. Subclinical renal disease may also occur. Vasculitis is often accompanied by adverse sequelae such as cellulitis, thrombophlebitis, laminitis, and pneumonia. Characterized vasculitis syndromes with predominant cutaneous involvement in horses include equine purpura hemorrhagica (EPH), equine viral arteritis (EVA), equine infectious anemia (EIA), and equine granulocytic ehrlichiosis (EGE). In addition, for a number of vasculitis syndromes in horses, the cause, pathogenesis, and clinical course are poorly defined.[46,47]

Vasculitis is apparently uncommon in ruminants but may accompany certain septicemic diseases, such as malignant catarrhal fever of cattle and bluetongue of sheep.[48]

Hematologic and serum biochemical findings in vasculitis are determined by the underlying disease, length of illness, organ involvement, and secondary complications. Chronic inflammation may involve neutrophilia, mild anemia, hyperglobulinemia, and hyperfibrinogenemia. Some horses with EPH develop a moderate anemia (PCV, 20% to 25%) thought to be caused by increased erythrocyte destruction.[49] The platelet count is generally normal. Muscle damage may be reflected by increased serum concentrations of creatine phosphokinase (CPK) and aspartate aminotransferase (AST). The creatinine may be elevated, and urinalysis may rarely show trace hematuria or proteinuria if there is glomerulonephritis.

The definitive diagnosis of vasculitis is made by demonstration of the characteristic histopathology of involved vessels. Full-thickness punch biopsies (at least 6 mm in diameter) of skin in an affected area should be obtained and preserved in 10% formalin and Michel's transport medium. Multiple biopsies from different sites may be necessary to reach the diagnosis. The most common inflammatory pattern is neutrophilic infiltration of venules in the dermis and subcutaneous tissue, with nuclear debris in and around involved vessels (leukocytoclasis) and fibrinoid necrosis. Immunofluorescence on biopsies preserved in Michel's medium may reveal immune complexes. Considerable evidence suggests that most vasculitis syndromes are mediated by immunologic mechanisms, that is, an allergic reaction to a microbe, drug, toxin, or protein.[44] In some cases an exogenous stimulus cannot be identified, and an autoimmune pathogenesis is suspected. Immune complex deposition in vessel walls, with subsequent complement activation and chemoattractant production, seems to be the major pathogenic mechanism. Infiltrating neutrophils and macrophages release proteolytic enzymes that cause vessel wall necrosis, with subsequent edema, hemorrhage, and infarction of supplied tissues. Size and physiochemical properties of immune complexes, blood flow turbulence in sites of vessel bifurcation, and hydrostatic forces in dependent areas account for preferential formation of lesions in certain disease states and anatomic locations. Horses and cattle with idiopathic vasculitis may have incomplete response to therapy with an unpredictable, poor prognosis.[48,49]

37.4.4.1.1

Equine Purpura Hemorrhagica (MA, DDM)

EPH is a noncontagious disease of horses characterized by vasculitis leading to extensive edema and hemorrhage of the mucosa and subcutaneous tissue. The disease has been recognized as a sequela to infection or exposure to *Streptococcus equi, S. zooepidemicus, Rhodococcus equi, Corynebacterium pseudotuberculosis,* and other species and to vaccination against *S. equi*.[45,50]

Young to middle-aged horses are usually affected (mean, 8.4 years; range, 6 months to 19 years).[50] The clinical signs usually develop acutely within 2 to 4 weeks of a respiratory infection.[51] The predominant signs are well demarcated subcutaneous edema of all four limbs, lethargy, anorexia, hemorrhages on mucous membranes, fever, and tachycardia. Other signs include tachypnea, reluctance to move, exudation from the skin, colic, and epistaxis.

The predominant laboratory abnormalities include anemia, neutrophilia, hyperproteinemia, hyperfibrinogenemia, hyperglobulinemia, and elevated muscle enzymes. Thrombocytopenia is rarely detected in horses with EPH.

Skin biopsy shows evidence of acute leukocytoclastic or nonleukocytoclastic vasculitis with necrosis of blood vessels. The lesions consist of marked dermal and subcutaneous hemorrhage, protein-rich edema, and multifocal areas of dermal infarction. Small arteries and capillaries are swollen and infiltrated by degenerate or nondegenerate neutrophils. Hyaline thrombi may be observed.[50] Immune complexes primarily composed of IgM or IgA, and streptococcal M protein may be present in capillaries and small blood vessels of horses with EPH, leading to type III hypersensitivity reaction.[52] Deposition of complement in immune complexes in vessel walls may result in cell death. Extensive hemorrhages in the dermis, subcutis, skeletal muscles, lungs, kidneys, spleen, intestinal walls, and blood vessels have been observed on postmortem examination.

Horses with infarctive EPH can present with colic, lameness, muscle swelling, and stiffness.[53] Extensive GI infarction results in severe colic signs. The significant findings in these horses include leukocytoclastic vasculitis and necrosis of various tissues, neutrophilia with a left shift, hypoalbuminemia, and high serum creatine kinase.[53]

1148

1149

Treatment is initiated to address the primary cause if identified, reduce the immune and inflammatory response, and provide antimicrobial therapy in cases of active infection, or to prevent infection if indicated, provide supportive care, and prevent complications. Horses with known streptococcal infection should receive penicillin (22,000 IU/kg of procaine penicillin G intramuscularly [IM] twice daily, or potassium penicillin G intravenously [IV] every 6 hours) for at least 2 weeks. Hydrotherapy, limb bandages, and light exercise (hand walk) have been helpful in reducing limb edema. Fluids administered through nasogastric tube or IV may be necessary for animals that become severely lethargic and fail to drink or those that develop dysphagia from laryngeal edema. Stridor and dyspnea may indicate the need for tracheostomy. Prolonged treatment with corticosteroids (2 to 4 weeks) has resulted in favorable outcome and low relapse rate. However, some horses may require more than 4 weeks. Depending on severity of clinical signs, proposed dosage is 0.04 to 0.2 mg/kg of dexamethasone (IV, IM, or orally [PO]) once (morning) or twice daily, or 0.5 to 1.0 mg/kg of prednisolone PO once (morning) or twice daily, with a gradual reduction of the dosage.[50] Use of antimicrobials has been suggested throughout corticosteroid therapy to reduce the prevalence of secondary sepsis.[45]

The outcome will depend on early detection, early aggressive treatment, and extent of organ involvement. Skin sloughing, laminitis, cellulitis, pneumonia, and diarrhea may be seen and may significantly prolong convalescence. Although the prognosis has been thought to be fair with early aggressive therapy and supportive care, a recent retrospective study of 53 horses with EPH reported a mortality rate of 7.5%.[50]

37.4.4.1.2

Equine Viral Arteritis (MA)

EVA is an infectious disease characterized by panvasculitis, edema, hemorrhage, and abortion in pregnant mares. EVA is caused by an enveloped, spherical, positive-stranded RNA virus with a diameter of 50 to 70 nm. Equine arteritis virus (EAV) is a non-arthropod-borne virus classified as a member of the new order Nidovirales within the family Arteriviridae.[54] EAV was first isolated from fetal lung collected during an epizootic of abortion in Bucyrus, Ohio.[55] Clinical signs may be absent or may develop 1 to 10 days after infection and include pyrexia, lethargy, anorexia, limb edema, stiffness, rhinorrhea, epiphora, conjunctivitis, rhinitis, and abortion. Edema of several regions may be observed, including periorbital, supraorbital, ventral abdomen, mammary gland, scrotum, and limbs.[56] Other signs include urticarial rash, abortion, respiratory signs, ataxia, mucosal eruptions, submaxillary lymphadenopathy, and intermandibular and shoulder edema. EAV can present as epidemic abortion, with occasional fatalities in foals and adults. In natural exposure, abortion rate varies from less than 10% to more than 60% and can occur from 3 to 10 months of gestation.[57] Infected mares do not become EAV carriers or chronic shedders and do not appear to have fertility problems.

Laboratory abnormalities are variable and not diagnostic for EVA. Experimentally infected mature horses had a consistent leukopenia from neutropenia and lymphopenia.[58] After infection, EAV can be localized in macrophages and lymph nodes within 24 and 48 hours, respectively. Various tissues are affected, but blood vessels are the principal target of EAV. Within vessels, EAV localizes in endothelium, medial myocytes, and pericytes. The virus causes vasculitis with fibrinoid necrosis of tunica media, abundant vascular and perivascular lymphocytic and lesser granulocytic infiltration with karyorrhexis, loss of endothelium, and formation of large, fibrinocellular, stratified thrombi.[56] Body cavity effusion may be seen.

The virus is mainly transmitted through aerosols from respiratory, urinary, or aborted secretions of acutely infected animals. The other route of transmission is through semen from shedding stallion. The virus remains viable in fresh, chilled, and frozen semen.[57] Horizontal transmission by fomites is possible.[59] Natural EAV exposure results in long-term immunity to disease. Mares and geldings eliminate virus within 60 days, but 30% to 60% of acutely infected stallions will become persistently infected, temporarily or permanently shedding virus in the semen.[56] The virus is maintained in the accessory organs of the male reproductive tract (ampullae, vasa deferentia).[57] An outbreak of EVA occurred in the quarter horse population in 2006.[60]

A fourfold or more increase in serum neutralizing antibodies between acute and convalescent samples (3 weeks apart) is required for diagnosis. Stallions with positive titers of 1:4 should be tested for persistent infection by virus isolation from sperm-rich ejaculate.[57] Viral isolation can be attempted from fetal and placental tissues. Semen can be tested for viral shedding by culture, isolation, or polymerase chain reaction (PCR). Identification of carrier stallions is crucial in preventing dissemination of EAV. A modified live

vaccine is available.* Vaccination will result in the development of a serum titer that will be detected on EVA testing and cannot be distinguished from active infection. Horses vaccinated for the first time may temporarily shed the modified virus.

37.4.4.1.3 Equine Infectious Anemia

See section on hemolytic anemia.

37.4.4.2 *ANAPLASMA PHAGOCYTOPHILA* INFECTION IN HORSES (MA, JEM)

37.4.4.2.1 Definition and Etiology

Equine granulocytic ehrlichiosis (EGE) was first reported in the late 1960s in the foothills of northern California.[61] The disease is caused by *Anaplasma phagocytophila,* formerly known as *Ehrlichia equi* but reclassified in the *Anaplasma* genus based on genetic analysis.[62] Recently, the agent of human granulocytic ehrlichiosis (HGE)—*Ehrlichia phagocytophila*—and *E. equi* have been grouped into a single species and named *Anaplasma phagocytophila*.[62] These organisms are identical based on 16S rRNA gene sequences and have similar morphology, host cell tropism, and indirect fluorescent antibody (IFA) response.[63] Furthermore, injection of infected blood from patients with HGE into horses causes EGE.

The organism is found within vacuoles (1.5 to 5 μm in diameter) in the cytoplasm of infected granulocytes, primarily neutrophils and eosinophils. These vacuoles, or inclusion bodies, are pleomorphic and contain one or more coccibacilli or large, granular aggregates called *morulae*. The organisms are visible under light microscopy as deep-blue to pale-blue gray with Giemsa or Wright-Leishman stains.

37.4.5 Epidemiology

Since the disease was first reported in California,[64] cases have been diagnosed in Colorado, Connecticut,[65] Florida, Illinois, Minnesota, New Jersey, New York, Oregon, Washington, Wisconsin, Canada, Brazil, northern Europe, and Israel. Equine cases occur during late fall, winter, and spring. There is no apparent gender or age predilection. However, EGE appears to be less severe in younger horses. Persistent, chronic, or latent infections and carrier status have not been demonstrated and are unlikely to occur because the presence of *A. phagocytophila* is limited to the acute phase. Therefore, it is also unlikely that infected horses could serve as reservoirs. The disease is not contagious but could be readily transmitted through the administration of infected blood. The vectors of granulocytic ehrlichiosis are *Ixodes pacificus* in California, *Ixodes scapularis* in the East and Midwest (U.S.), and *Ixodes ricinus* in Europe.[66–69] Potential or proposed reservoirs are white-footed mice, chipmunks, white-tailed deer, dusky-footed wood rats, cervids, lizards, and birds.[69]

1149 1150

37.4.6 Pathogenesis

The pathogenesis of EGE is unknown. Entry of the organism occurs after inoculation from a biting tick and presumed spread by blood and lymphatics. The organism has cell tropism toward neutrophils and eosinophils, where it replicates within vacuoles, forming characteristic morulae. Presumed cytolysis, induction of inflammation, and cell sequestration, consumption, or destruction result in the observed clinical signs and

pancytopenia.[70] Cell-mediated and humoral-mediated immune responses develop in affected animals. Antibody titers peak at 19 to 81 days after the onset of clinical signs, and immunity may persist for a long time (2 years).[71]

37.4.7 Clinical Signs

Signs include reluctance to move, fever ranging from 39.4° to 41.3° C (102.9° to 106.3° F), mild to moderate tachycardia (50 to 60 beats/min), lethargy, decreased appetite, limb edema, petechiation, icterus, weakness, ataxia, and recumbency (reported in one case). Secondary trauma may result from falling in severely ataxic horses. These clinical signs appear to be less profound in younger horses. The presumptive incubation period after natural infection is believed to be less than 14 days. The prepatent period after experimental exposure to infected ticks or inoculation with infected blood is 8 to 12 days and 3 to 10 days, respectively. The disease is self-limiting and nonfatal provided no complications develop. However, affected horses may be predisposed to secondary bacterial, fungal, and viral infections.[61] Abortions and laminitis have not been reported in affected horses.

37.4.8 Clinical Pathology

Laboratory alterations include anemia, leukopenia characterized by granulocytopenia and lymphopenia, and thrombocytopenia. Morulae may be observed within the cytoplasm of neutrophils and eosinophils during the acute phase of the infection.

37.4.9 Diagnosis

The definitive diagnosis is based on the presence of characteristic morulae (minimum of three) within the cytoplasm of neutrophils and eosinophils or positive PCR assay for *A. phagocytophila* in peripheral blood (buffy coat).[72] Morulae may be observed in less than 1% of cells in the initial stages of the infection, up to 20% to 50% of the cells few days later. A-fourfold or greater increase in IFA titer of paired samples confirms recent exposure.[73]

37.4.10 Pathologic Findings

Petechiae and ecchymosis of subcutaneous tissues and edema of the ventral abdomen, limbs, and prepuce are characteristic in infected animals. Proliferative and necrotizing vasculitis, thromboses, and perivascular cuffing in subcutaneous tissue, fascia, kidneys, heart, brain, lungs, ovaries, and testes have been reported.[61,70]

37.4.11 Treatment, Prognosis, and Prevention

The treatment of choice is IV oxytetracycline, 7 mg/kg once daily for 5 to 7 days. Prompt response to treatment is seen within the first 24 hours. Supportive therapy may be necessary in some cases. The disease can be self-limiting in 2 to 3 weeks if untreated. The prognosis of the disease is excellent provided secondary complications are prevented. At present, prevention is limited to tick control.

37.4.11.1

THROMBOCYTOPENIA (DDM)

Thrombocytopenia (platelet count <100,000/μL) can result from one or more of three basic mechanisms: (1) decreased or ineffective platelet production, (2) abnormal sequestration (usually in spleen), or (3) shortened platelet survival (consumption or destruction). Thrombocytopenia causes a hemorrhagic diathesis characterized by multiple sites of small-vessel bleeding. Petechial hemorrhages with or without ecchymotic hemorrhages are generally found on the oral, nasal, or vaginal mucous membranes, as well as on the nictitans and sclera. Epistaxis, melena, hyphema, or microscopic hematuria may occur, but spontaneous hemorrhage is unusual unless the platelet count is less than 10,000/μL. Prolonged bleeding from wounds, injections, or surgical procedures and the propensity to form hematomas after minor trauma are common when the platelet count drops below 40,000/μL. The platelet count below which bleeding occurs varies among individuals and seems to be determined by concurrent diseases.

The interaction of blood platelets with a discontinuous vascular surface constitutes the basis for primary hemostasis. In addition, platelets provide the phospholipoprotein surface necessary to catalyze interactions among the activated coagulation proteins that culminate in fibrin formation. The platelet surface also protects activated clotting factors from destruction by plasma anticoagulants, thereby localizing coagulation to the hemostatic plug. Finally, platelets maintain “vascular integrity” through obscure mechanisms and prevent spontaneous hemorrhage into the skin and mucous membranes. Severe thrombocytopenia produces prolonged bleeding time and abnormal clot retraction without affecting clotting times or plasma fibrinogen.

Persistent life-threatening hemorrhage caused by thrombocytopenia may be treated with a transfusion of compatible fresh whole blood or, preferably, PRP, which may be produced by centrifugation thrombocytopheresis[74] or by centrifugation of freshly collected blood, 3 to 5 minutes at 250 *g*.[75] Blood or plasma must be used immediately and contact with glass prevented to avoid platelet adhesion and activation. Platelet transfusion is a very transient lifesaving measure, and the ultimate prognosis for thrombocytopenia depends on the cause.

Decreased production of platelets may result from replacement of the normal marrow architecture by neoplastic or inflammatory tissue (myelophthisic disease) or from bone marrow aplasia. Both conditions are characterized by peripheral pancytopenia of variable severity and are extremely unusual in large animals. Myelophthisic disease with thrombocytopenia has been described in horses with various forms of myelogenous neoplasia[76–78] and eosinophilic myeloproliferative disorder.[79]

Hypoplastic anemia with leukopenia and thrombocytopenia has been reported in horses and cattle, as discussed later under Aplastic Anemia. Shortened platelet lifespan is by far the most common cause of thrombocytopenia in large animals. Increased platelet consumption accompanies DIC (discussed in the next section) and rare cases of vasculitis. Immune-mediated mechanisms result in platelet destruction.

Immune-mediated thrombocytopenia (IMTP) may be primary (idiopathic) or secondary to drug administration, infections, neoplasia, or other immunologic disorders.[75] This disease is most common in horses and has been reported secondary to EIA,[80] lymphoma,[81] and autoimmune hemolytic anemia.[82] The clinical signs of IMTP include mucosal hemorrhages and the propensity to bleed from small blood vessels. Horses with idiopathic IMTP are usually bright, afebrile, and without overt hemorrhage despite severely reduced platelet numbers. Thrombocytopenia in a horse with obvious primary disease should prompt a thorough hemostatic workup to rule out DIC.

1150
1151

Alloimmune thrombocytopenia of neonates has been recognized as a spontaneous disease of human infants, piglets, foals, and possibly mule foals.[83] Clinical signs include depression, loss of suckle, a bleeding tendency, blood loss, and rapidly developing anemia because of a profound thrombocytopenia. The condition occurs in multiparous dams, and immunoglobulins may be found in the mare's plasma, serum, and milk that bind to the foal's platelets. Alloimmune thrombocytopenia should be considered in neonates with severe thrombocytopenia when other causes can be excluded, and platelet antibody assays should be used to support this diagnosis. Differential considerations include neonatal sepsis, neonatal maladjustment syndrome, and neonatal isoerythrolysis.

Laboratory findings of IMTP include severe thrombocytopenia (<40,000/μL), prolonged bleeding time, and abnormal clot retraction with normal TT, PT, aPTT, and plasma fibrinogen. FDPs may be mildly increased, and anemia with hypoproteinemia develops if blood loss is ongoing. In most cases of IMTP and other causes of shortened platelet lifespan, megakaryocytic hyperplasia is evident on examination of bone marrow aspirates or biopsies. Megakaryocytic destruction by the immunologic process could induce megakaryocytic hypoplasia, although this is apparently rare in horses.

The definitive diagnosis of IMTP requires demonstration of increased quantities of platelet-associated IgG or C3 or antiplatelet activity in the serum. Unfortunately, methods to detect platelet-associated immunoreactants have not been adapted for horses, although it appears they affect platelet function.[84] Therefore the diagnosis of IMTP must be based on small-vessel hemorrhagic diathesis and severe thrombocytopenia in a horse with normal coagulation times and no other evidence of DIC. Response to therapy (see next section) supports the diagnosis. A tentative diagnosis of IMTP in the horse should prompt a thorough search for an underlying disorder, especially lymphoma.

Platelet destruction in IMTP is apparently mediated by antibodies coating the platelet surface that cause premature platelet removal from circulation by the mononuclear phagocyte system (MPS).[85] In *primary* IMTP the platelet-associated immunoglobulin is directed against a membrane antigen, is usually of the IgG class, is produced in the spleen, fixes complement, and can be absorbed from serum by platelets from a normal individual of the same species. Autoantibodies may attach to megakaryocytes, but the latter are not necessarily destroyed because they do not circulate through the spleen or liver. In *secondary* IMTP the immunoglobulin bound to the platelet surface is part of an immune complex composed of antibody directed against a drug, microbe, or neoplastic antigen that is nonspecifically attached to the platelet Fc receptor. For secondary IMTP to be perpetuated, the foreign antigen must be constantly replenished or difficult to excrete. Drug-induced IMTP generally subsides within a few days of drug discontinuation, although thrombocytopenia secondary to chrysotherapy (gold therapy) may persist for weeks to years. Because gold is occasionally used to treat pemphigus foliaceus in horses, thrombocytopenia should be considered as a potential side effect. The spleen is the major site of platelet phagocytosis because (1) much antiplatelet antibody is secreted locally, (2) more than 30% of circulating platelets are normally stored there, and (3) the stagnant splenic blood flow allows sensitized platelets to pass slowly through a dense network of phagocytic cells. The mean cell life of circulating platelets and the platelet count are inversely proportional to the quantity of platelet-associated IgG.

When any unexplained case of thrombocytopenia is treated, all current medication should be stopped. If a drug is absolutely necessary, it must be replaced by the chemically most-dissimilar substitute. Drug-induced IMTP usually responds within 14 days of drug withdrawal. Most animals with suspected IMTP improve when treated with corticosteroids. Although their precise mechanisms of action are speculative, corticosteroids improve capillary integrity, impair clearance by the MPS, decrease the number and avidity of

macrophage Fc receptors, impair antiplatelet antibody production, impede platelet-antibody interactions, and increase thrombocytopoiesis.

Dexamethasone (0.05 to 0.2 mg/kg IV or IM) given once daily generally results in an elevation in the platelet count within 4 to 7 days. Once the platelet count is greater than 100,000/μL, the dose of dexamethasone can be reduced by 10% to 20% daily, while the platelet count is monitored for a relapse. Occasionally, animals with IMTP are refractory to dexamethasone, in which case prednisolone (1 mg/kg IM twice daily) may be tried. Treatment with corticosteroids can usually be discontinued after 10 to 21 days, provided the platelet count has been normal for at least 5 days.

Most horses with IMTP have a favorable prognosis, and the disease resolves within 14 to 21 days. This suggests that many cases may be secondary, although the initiating cause is rarely found. Chronic or recurrent IMTP requiring prolonged corticosteroid therapy has been reported.[86] Alternative treatment modalities for IMTP are largely unproved in horses because most cases respond to corticosteroids.[87–89]

37.4.11.2

DISORDERS OF COAGULATION FACTORS (DDM)

Normal blood coagulation proceeds in an integrated sequence that can be simplistically viewed as three key reactions: formation of activated factor X, formation of thrombin, and formation of fibrin. Other protein interactions serve to accelerate or inhibit the reaction rate of the coagulation factors.[26] Excessive use or inhibition of these proteins produces a relative deficiency that causes hemorrhagic diathesis. Alterations in the coagulation cascade, including thrombocytopenia and procoagulant and anticoagulant effects, can be observed with snakebite (e.g., rattlesnake) envenomation (see Chapter 54).

37.4.11.2.1

Disseminated Intravascular Coagulation

The most common form of hemostatic dysfunction in large animals is a syndrome known variously as DIC, consumption coagulopathy, defibrination syndrome, or intravascular coagulation fibrinolysis.[90–91] The pathologic process is characterized by widespread fibrin deposition in the microcirculation, with subsequent ischemic damage, and the development of a hemorrhagic diathesis caused by the consumption of procoagulants and hyperactivity of fibrinolysis.[26] Never a primary disease entity, DIC represents an intermediary mechanism of underlying disease. In large animals, DIC has been described in association with forms of localized or systemic septic processes,[91–94] neoplasia,[91] GI disorders,[49,95] renal disease,[95] and hemolytic anemia.[94,96] Diffuse activation of the hemostatic system is particularly prevalent in horses with acute GI disorders that cause colic[31,94,95] and is a likely initiating factor for laminitis.[97,98] Because of the dynamic nature of DIC, clinical manifestations range from diffuse thrombosis leading to ischemic organ failure to severe hemorrhagic diathesis. The most important determinants are the rate of thrombin generation, which depends on the triggering disease, adequacy of fibrinolysis, and functional state of the MPS, which is largely determined by peripheral circulation. Coagulopathy usually occurs in a compensated form in horses and cattle and is rarely accompanied by overt hemorrhage; however, microvascular thrombosis and subsequent ischemia to vital tissues leads to organ malfunction (e.g., renal failure), which contributes to the morbidity and mortality of the primary disease process.

1151

1152

Renal involvement is common in DIC, which produces ischemic cortical necrosis followed by acute tubular necrosis. Renal disease may be manifested by oliguria, depression, and ileus caused by azotemia and electrolyte imbalances. GI microthrombosis may induce colic as a result of submucosal necrosis and

superficial ulceration. Spontaneous GI hemorrhage caused by DIC may cause melena in ruminants and occult fecal blood loss in horses. Rarely, pulmonary function may be compromised by microvascular thrombosis in DIC, causing tachypnea and variable hypoxemia. Altered consciousness, delirium, convulsions, or coma may follow cerebral microvascular thrombosis, although these signs are not common in large animals with DIC. Although reported in both horses[99] and cattle,[96] microangiopathic hemolysis is rare in large animals with DIC because of their small erythrocyte size.

Digital ischemia frequently accompanies DIC in horses and may play a role in the development of acute laminitis. Laboratory evidence of DIC has been documented during the developmental phase of equine laminitis,[98] and digital microvascular thrombosis occurs in horses that develop laminitis with colic or septic conditions.[97] The tendency for thrombosis of major peripheral veins is another prominent manifestation of coagulopathy in horses. Venous thrombosis occurs in horses and is associated with needle- or catheter-induced intimal trauma, nonsterility during catheterization, blood sampling or treatment procedures, and thrombogenic catheter materials. However, the strong clinical impression remains that severely ill horses with diseases known to induce coagulopathy have a greater tendency toward venous thrombosis. Spontaneous thrombosis of smaller cutaneous vessels also occurs.

As the thrombotic stimulus continues or intensifies, the tendency for hemorrhage develops because of clotting factors and platelet depletion or generation of excessive fibrinolytic by-products (FDPs). Petechial or ecchymotic hemorrhages on mucosae and sclerae and a tendency to bleed from venipuncture or after minor trauma are the principal signs. Spontaneous life-threatening hemorrhage is very rare; however, trauma or surgery may induce uncontrollable hemorrhage. Once signs of blood incoagulability develop, the prognosis is poor.

Horses may develop a chronic, compensated form of DIC with few or no clinical signs. This entity develops in patients with illnesses that produce a low-grade or intermittent procoagulant stimulus that allows used coagulant proteins and platelets to be partially or totally replenished and activated clotting factors and FDPs to be cleared by the MPS. Localized sepsis (e.g., pleuritis), neoplasia, protein-losing enteropathy, and immune-mediated disorders (vasculitis, anemia) are common initiating diseases. This compensated state may become imbalanced by stress, concurrent diseases, or worsening of the primary process, resulting in clinically obvious DIC. Diseases that must be differentiated from DIC include IMTP, warfarin toxicosis (horses), moldy sweet clover toxicosis, and inherited coagulation abnormalities.

Numerous laboratory tests of hemostasis may be abnormal during DIC; however, no one test consistently or specifically provides a definitive diagnosis. Lack of test sensitivity results from the dynamic nature of DIC; laboratory findings are determined by the balance between coagulation and fibrinolytic forces, as well as MPS integrity at blood sampling.

The most widely used hemostatic function tests in large animals include the platelet count, plasma fibrinogen, PT, aPTT, and serum FDPs. Because clinical manifestations of DIC vary widely, clarification of the most frequent laboratory abnormalities in large animals with DIC is hindered by lack of a definitive diagnosis in most cases. A disseminated coagulopathy is manifested by multiple hemostatic abnormalities, and serial analyses should reveal reduced platelet numbers and a trend toward prolongation of the PT, aPTT, and TT. Repeated hemostatic testing is advised when there is strong suspicion for DIC. Serum FDPs are most often elevated by DIC, but they are usually normal in the early or compensated form of the disease. Hypofibrinogenemia is an uncommon manifestation of DIC in large animals and, when present, should strongly suggest concomitant liver dysfunction. Hemostatic function tests are totally unreliable unless blood samples are collected and handled properly.

Criteria used for diagnosis of DIC are extremely arbitrary, and laboratory results must be interpreted in light of the patient's underlying disease. The combination of thrombocytopenia with mild to moderate prolongation of the PT or aPTT strongly suggests DIC. The clinician should seek laboratory assistance when considering the diagnosis of DIC but should appreciate that the findings are often not helpful. Clinical signs and specific situations suggest the possibility of DIC, and laboratory tests are only used to provide support.

Diseases initiate DIC by two major mechanisms: (1) generation of excessive procoagulant activity within the blood and (2) contact of blood with abnormal surfaces. Many diseases act by more than one mechanism to induce the overwhelming stimulus needed to trigger DIC. The nature and intensity of the procoagulant force (which determines the rate of thrombin formation), the concentration of natural coagulation inhibitors, and the functional capacity of the MPS determine (1) whether an individual with a given disease process develops DIC and (2) the clinical manifestations of DIC. Many diseases that produce DIC have the propensity to cause endotoxemia. The intestinal tract in large animals normally contains large quantities of endotoxins, only a small part of which is absorbed through the portal vein and removed by the liver. Conditions that cause intestinal mucosal edema or disruption allow endotoxins to gain access to the peripheral circulation and initiate many morbid sequelae, one of which is DIC. Intestinal strangulating obstruction, thromboembolic infarction, and severe colitis induce mucosal abnormalities, allowing endotoxemia to occur. The proliferation of gram-negative bacteria within tissues and the blood is also accompanied by endotoxemia.

Gram-negative endotoxins are capable of direct factor XII activation. However, most studies indicate that the procoagulant effects of endotoxin are primarily mediated by cytokine production by mononuclear phagocytes.[27,100] After endotoxin stimulation, phagocytes produce a platelet-activating factor (PAF), tissue factor, prostaglandins, interleukins, tumor necrosis factor (TNF), and other mediators with procoagulant activity.[27,101]

The net result of any triggering mechanism for DIC is the exaggerated generation of systemic thrombin, which causes widespread microcirculatory thrombosis. In addition to the cleavage of fibrinogen to produce fibrin monomers, thrombin activates factor XIII to render fibrin more resistant to fibrinolysis, enhances the cofactor activity of factors V and VIII, and induces platelet aggregation and exposure of platelet phospholipid. Circulatory obstruction produces organ hypoperfusion, leading to ischemic necrosis.

The counterbalance fibrinolytic system is also activated by DIC and plasmin contributes to factor consumption by destroying factors V, VIII, XIIa, IX, and XI, in addition to fibrin and fibrinogen. FDPs contribute greatly to the hemorrhagic manifestations of DIC because they have antithrombin activity, interfere with fibrin monomer polymerization, and cause platelet dysfunction.[28] Paradoxically, the combination of consumption and anticoagulation predisposes to hemorrhage at the same time that disseminated thromboses occur.

1152
1153

The MPS plays a vital role in the pathogenesis of DIC. The tissue-fixed macrophages of the spleen and liver normally remove FDPs and activated clotting factors from the peripheral circulation, and FDPs only increase when their rate of formation exceeds the ability of the MPS to clear them. Shock and hypoperfusion of the liver and spleen or diseases associated with excessive tissue debris that must be removed by the MPS (e.g., sepsis, metastatic neoplasia) reduce the function of the MPS and predispose to or perpetuate DIC.

Therapy for DIC is highly controversial, and the only noncontended modalities are those directed toward identification and treatment of the primary disorder, along with general supportive measures to combat shock and maintain tissue perfusion.[26,88,102,103] Intravenous fluid administration helps to prevent organ dysfunction after microvascular thrombosis and can correct existing acid-base or electrolyte imbalances. Septic conditions should be treated with appropriate antimicrobial agents, and necrotic tissue or purulent exudate removed whenever possible (e.g., immediate surgical intervention to resect nonviable bowel). Flunixin meglumine mitigates the deleterious effects of endotoxin caused by eicosanoids and is used in horses at 0.25 mg/kg IV every 8 hours.[49] Corticosteroids may worsen DIC because they reduce the phagocytic action of the MPS and potentiate the vasoconstrictor effects of catecholamines.

Significant life-threatening hemorrhage is rare in large animals with DIC; however, if it occurs, fresh plasma should be administered (15 to 30 mL/kg) to replace used coagulant and anticoagulant proteins. The use of heparin in DIC has been recommended in various regimens to stall the disseminated microvascular thrombosis that precipitates organ failure; however, its efficacy is still controversial.[88,103] In dogs, minidose heparin therapy (5 to 10 U/kg subcutaneously [SC] three times daily) is often used with blood products in treatment of DIC.[88,102] Efficacy of heparin for DIC in horses is unproven. Heparin in all species can predispose to hemorrhage, thrombosis, and thrombocytopenia[104] and causes anemia and erythrocyte agglutination in horses.[105] If considering heparin therapy, the clinician must ensure there is adequate plasma AT III, which is necessary for heparin action. Because AT III is often depleted by DIC, plasma may be necessary. Clinical trials in humans have not indicated therapeutic benefit of anticoagulants in chronic DIC.

The prognosis for DIC in large animals depends largely on the nature and severity of the underlying disease and how effectively the latter is treated. Once DIC has progressed to the stage at which signs of blood incoagulability predominate, the prognosis generally is extremely poor.

37.4.11.2.2

Warfarin Toxicosis

Horses may develop a hemorrhagic diathesis caused by warfarin toxicosis.[106] Some use this coumarin-derivative anticoagulant to treat horses with navicular disease.[107] Rarely, horses and other animals may be exposed to coumarins used as rodenticides in grains or other feedstuffs. Therapeutic concentrations of warfarin can have a cumulative toxic effect if the diet is altered to contain less vitamin K or if there is concurrent protein-bound drug therapy. The clinical signs of warfarin toxicosis include hematomas, ecchymoses of mucous membranes, epistaxis, and hematuria. The earliest laboratory indication of warfarin toxicosis is a prolongation of PT because the plasma half-life of factor VII is shorter than the other clotting factors.[108] As the disease progresses, the aPTT becomes prolonged, and the animal may develop blood-loss anemia and hypoproteinemia. The diagnosis of warfarin toxicosis is based on a history of exposure, clinical signs of large-vessel hemorrhagic diathesis, and prolonged PT with or without aPTT and with no other abnormalities of the clotting profile.

Warfarin acts through competitive inhibition of vitamin K, which is necessary for liver production of clotting factors II, VII, IX, and X.[107] Factor activity is reduced in the blood at a rate that depends on its individual half-life. In most species, factors VII, IX, X, and XI have increasingly greater half-lives, accounting for the greater sensitivity of PT for the early diagnosis of warfarin toxicosis. After GI absorption, warfarin is highly bound to plasma proteins. Drugs that are normally protein bound (e.g.,

phenylbutazone, chloral hydrate) can enhance the toxicity of warfarin by allowing a greater proportion of the administered drug to be unbound and active.[109] In the same manner, hypoalbuminemia may increase the likelihood of warfarin toxicosis. Corticosteroids and thyroxin can lower the necessary therapeutic dose of warfarin by increasing both the receptor affinity and the clotting factor catabolism. Drugs that induce hepatic microsomal enzyme activity (e.g., barbiturates, rifampin, chloramphenicol) can accelerate warfarin metabolism and reduce therapeutic response to a given dose. Finally, any reduction in hepatic function or content of vitamin K in the diet can precipitate warfarin toxicosis.

Treatment of warfarin toxicosis depends on clinical signs. Warfarin therapy should be stopped if PT exceeds twice the pretherapeutic value. Vitamin K_1 (0.5 to 1 mg/kg SC) must be given every 6 hours until PT is again normal and stable. Significant hemorrhage can be controlled by the administration of fresh plasma to provide necessary clotting factors. If the anemia is life threatening, whole-blood transfusion should be considered. Although warfarin is eliminated rapidly, some potentiated coumarins have a prolonged half-life, requiring a longer course of vitamin K therapy. The prognosis for warfarin toxicosis is good with early diagnosis and prompt administration of vitamin K. It is imperative that vitamin K_3 not be used because it has poor therapeutic action and is highly nephrotoxic for horses.[110]

Prevention of warfarin toxicosis is based on limiting access of livestock to rodenticides and carefully monitoring the therapeutic use of warfarin in horses. The benefits of warfarin in horses are highly controversial, and many question whether advantages outweigh the risks.

37.4.11.2.3

Sweet Clover Toxicosis

Sweet clover (*Melilotus* species) toxicosis is caused by the ingestion of moldy sweet clover hay or silage containing dicoumarol. Natural coumarins in sweet clover can be converted to dicoumarol when hay or silage is improperly cured and mold forms. The toxin persists in moldy hay or silage and is palatable. This disease can occur in all species but is most often seen in cattle fed sweet clover hay in the northern plains states. Early signs include epistaxis and melena, with the development of subcutaneous hematomas and periarticular swellings as the disease progresses. Visible swellings occur at points of trauma (e.g., brisket, tuber coxae, carpi) and are not hot or painful, although they may cause stiffness and disinclination to move. Accidental and surgical wounds cause severe hemorrhage and may precipitate fatal blood-loss anemia.

Clinical pathology in sweet clover toxicosis is similar to that described for warfarin toxicosis, with prolonged PT being the earliest abnormality (detected before clinical evidence of hemorrhage). The platelet count remains normal, which differentiates this syndrome from DIC and bracken fern toxicosis. Other diagnostic rule-outs include mycotoxicosis, and toxicosis from trichloroethylene-extracted soybean meal.[48] In the absence of fever and anorexia, coagulopathy should make moldy sweet clover toxicosis a strong tentative diagnosis in animals with a history of access. Chemical analysis for dicoumarol in suspected feed or in the blood and liver of affected animals aids in the diagnosis[111]; however, the disease cannot be excluded if dicoumarol is not detected.

1153 1154

The pathogenesis of moldy sweet clover toxicosis is identical to that of warfarin toxicosis. Dicoumarol interferes with hepatic synthesis of clotting factors II, VII, IX, and X by inhibiting vitamin K. Usually the syndrome appears in cattle 2 to 7 days after they ingest the moldy hay. Lower levels of dicoumarol (<70 mg/kg) in feed may prolong the onset of signs for up to 3 months.[48]

The succulent nature of sweet clover creates a high incidence of molding in hay. Grazing the crop is not dangerous. Because of its high forage yield, sweet clover is usually harvested as silage, which should carry less danger of molding when properly cured. The toxic level of dicoumarol in sweet clover feed samples is 10 mg/kg of feed.[111]

Treatment of sweet clover toxicosis involves discontinuing the use of contaminated feed and administering vitamin K_1.[109] Dosages between 1.1 and 3.3 mg/kg should be administered IM; response occurs within 24 hours. Animals with severe blood-loss anemia or ongoing hemorrhage should be treated with plasma or whole fresh blood. Sweet clover toxicosis can be prevented by careful forage preparation, followed by the inspection of hay and silage before feeding. When the disease is suspected, questionable feed should be removed from the diet.

37.5 DISEASES ASSOCIATED WITH INCREASED ERYTHROCYTE DESTRUCTION (HEMOLYTIC ANEMIA)

GARY P. CARLSON

Hemolytic disorders are characterized by an increased rate of red blood cell (RBC, erythrocyte) destruction. Anemia occurs when the rate of RBC destruction exceeds the bone marrow capacity for increased proliferative response. Although intravascular hemolysis occurs in some circumstances, these anemias are primarily caused by an increased rate of extravascular erythrocyte destruction and shortened intravascular lifespan.

Hemolytic anemias are associated with a wide range of systemic disease processes. The mechanisms responsible for the enhanced RBC destruction also vary greatly. Box 37-1 lists differential considerations of possible causal factors for hemolytic anemia in large animals. Clinical manifestations of hemolytic anemia vary with the degree of anemia, rate of RBC destruction, and primary or underlying disease process. Regardless of the cause, however, several common clinical signs are seen in animals with a severe hemolytic anemia, including pallor of the mucous membranes, fatigue, depression, and anorexia. Clinical icterus can be quite variable, depending on the rate of RBC destruction and the ability of the liver to excrete bilirubin. Icterus is a characteristic feature in hemolytic anemia, but intense icterus is noted only after massive RBC destruction and often is transient. With continued low-level hemolytic processes, the liver may be able to excrete bilirubin at a rate sufficient to avoid clinical icterus. Hemolytic icterus must be differentiated from other potential causes, such as liver disease or anorexia, in horses. If icterus is caused by hemolytic processes, clear clinical and hematologic evidence of anemia should exist. Massive intravascular hemolysis may result in an orange to reddish discoloration of the mucous membranes. Modest to marked and often variable febrile responses are frequently encountered in hemolytic anemias caused by infectious agents and during periods of active erythrocyte destruction. With advanced anemia the pulse and respiratory rates are elevated at rest. Death losses may occur, and neurologic abnormalities ranging from bizarre behavior to mania, collapse, and death may be associated with handling animals with a severe anemia.

37.5.1 Box 37-1 Causes of Hemolytic Anemia

37.5.1.1 INFECTIOUS CAUSES

37.5.1.1.1 Parasitic

- Anaplasmosis
- Babesiosis
- Hemobartonellosis
- Eperythrozoonosis
- Theileriasis
- Trypanosomiasis

37.5.1.1.2 Bacterial

- Leptospirosis
- Bacillary hemoglobinuria

37.5.1.1.3 Viral

- Equine infectious anemia (EIA)

37.5.1.2 IMMUNE-MEDIATED HEMOLYTIC ANEMIA

- Autoimmune hemolytic anemia
- Neonatal isoerythrolysis (NI)
- Drug induced: penicillin, trimethoprim-sulfamethoxazole

37.5.1.3 HEINZ BODY HEMOLYTIC ANEMIA

Phenothiazine toxicity

Wild onion poisoning

Red maple leaf poisoning

37.5.1.4 OTHER CAUSES

Severe cutaneous burns

L-Tryptophan—indole intoxication

Water intoxication

Postparturient hemoglobinuria

Copper poisoning

Hemolytic syndrome in horses with liver failure

Erythropoietic porphyria in Holstein cattle

The hematologic manifestations of hemolytic anemia also vary with the rate of RBC destruction, time course of the anemia, and primary or underlying disease process. The anemia may be modest to severe; after the first few days in all species except the horse, there is usually hematologic evidence of enhanced erythropoietic response, manifested by increased anisocytosis, polychromasia, reticulocytosis, and the presence of nucleated RBCs in the circulation. Morphologic abnormalities of diagnostic significance (e.g., intracellular/epicellular parasites, granulocytic inclusion bodies, Heinz bodies, spherocytes, schistocytes, poikilocytes) may be noted on examination of stained blood smears. Responsive anemias often are accompanied by a neutrophilia and regenerative left shift. The bone marrow usually shows an active erythropoietic response with a decreased myeloid/erythroid (M/E) ratio. The serum concentration of haptoglobin is decreased, and serum lactate dehydrogenase (LDH) enzyme activity may be elevated during acute hemolytic episodes. An increase in serum bilirubin concentration, caused primarily by an increase in indirect reacting bilirubin, is a reflection of active RBC destruction. 1154 1155

Specific serologic diagnostic procedures are available for many of the infectious causes of hemolytic anemia. Immunohematologic procedures such as the direct and indirect Coombs' test show that immune-mediated processes contribute to enhanced erythrocyte destruction. The principal mechanisms responsible for increased rate of RBC destruction associated with many of the infectious causes of hemolytic anemia (parasitic, bacterial, viral) are immunologically mediated, and affected animals may be transiently Coombs' positive.

37.6 INFECTIOUS CAUSES OF HEMOLYTIC ANEMIA

37.6.1 Anaplasmosis

GUY PALMER

37.6.2 Definition and Etiology

In veterinary medicine, anaplasmosis traditionally refers to disease characterized by progressive anemia caused by intraerythrocytic infection with *Anaplasma marginale* in cattle and *Anaplasma ovis* in sheep and goats. In addition, *A. marginale* subspecies *centrale* (also known as *Anaplasma centrale*) causes mild disease in cattle and has been used as a live vaccine to induce partial protection against *A. marginale*.

In the recent taxonomic reclassification of the tick-borne bacteria in the genera *Anaplasma* and *Ehrlichia, Ehrlichia equi* (cause of equine granulocytic ehrlichiosis), *Ehrlichia phagocytophila* (the cause of tick-borne fever in sheep, not recognized as a significant disease problem in North America), and the agent of human granulocytic ehrlichiosis (HGE) have been reclassified and unified as a single species, *Anaplasma phagocytophila*.[62] Correspondingly, the disease caused by *A. phagocytophila* in humans is designated as human granulocytic anaplasmosis (HGA) and in horses as equine granulocytic anaplasmosis. In addition, *A. phagocytophila* is an emerging disease of dogs.[112] Although this discussion primarily addresses bovine anaplasmosis and, to a lesser degree, ovine and caprine anaplasmosis, it is important to emphasize that any descriptions of human anaplasmosis are in reference to infection with *A. phagocytophila*. There is no evidence that *A. marginale* or *A. ovis* are capable of infecting humans or any nonruminant mammalian species.

37.6.3 Clinical Signs and Differential Diagnosis

Clinical signs are highly variable, from acute severe disease to subclinical infection, and reflect variation in virulence among pathogen strains and age- and breed-related differences in host susceptibility. Age at the time of initial infection is a primary determinant of host susceptibility. Disease is often mild in calves in the first 6 to 9 months of life and increasingly severe in older cattle. The typical incubation period ranges from 15 to 30 days. Infections in calves are often asymptomatic, but mild lethargy and anorexia may be seen for 24 to 48 hours. In contrast, the early stage of acute anaplasmosis in adult cattle is typified by fever, with rectal temperatures ranging from 39.5° C to 41° C (103° F to 106° F). Within 12 to 24 hours the fever subsides, and the temperature may drop to normal and become subnormal before the animal dies. Anorexia and, in dairy cows, a dramatic decrease in milk production can usually be observed soon after a fever is detected. Concurrently, there is suppression of rumination, dryness of the muzzle, and lethargy. Cattle may stagger or become aggressive as a result of cerebral hypoxia associated with anemia. Care must be taken not to stress severely anemic cattle because this may result in collapse and death. Early, the mucous membranes are pallid, but they may be icteric if an animal has survived for 2 to 3 days past the acute crisis. Constipation is a consistent sign, with the feces dark brown and covered with mucus, and pollakiuria is characterized by dark-yellow urine. Hemoglobinuria does not occur. Abortion may occur when infection occurs late in gestation. If an animal survives the acute crisis, the convalescent period is protracted and depends on the severity of the anemia. Icterus and weight loss are more frequently observed in the convalescent period, which may last for 3 to 4 weeks. Recovered animals remain persistently infected for life and, as described later, are epidemiologically important as a reservoir for ongoing transmission. However, persistent infection is not

associated with any disease or decrease in production status; therefore, no basis exists for a diagnosis of "chronic anaplasmosis." Although *A. ovis* infection in sheep and goats is often asymptomatic, anemia occasionally becomes severe enough to produce signs similar to those seen during *A. marginale* infection of cattle.

Definitive diagnosis of acute anaplasmosis requires identification of *A. marginale*— or *A. ovis*—infected erythrocytes by microscopic examination of blood smears, concomitant with a significant decrease in hematocrit (see next section). The differential diagnosis requires consideration of the diseases that can produce anemia or icterus, including babesiosis, bacillary hemoglobinuria, and leptospirosis. In pastured cattle, hepatotoxic plant poisonings *(Senecio)* and other causes of liver disease that produce icterus must also be considered. Copper poisoning is considered in sheep.

37.6.4 Clinical Pathology and Serology

Because acute bovine anaplasmosis is characterized by anemia, a falling hematocrit is an excellent criterion for prognostic purposes and for determining the severity of infection. The packed cell volume (PCV) drops below 30% when the first clinical signs are observed and may drop precipitously within 24 to 48 hours. Death can occur during this period despite a PCV above 20%. In other cases, PCV may decrease below 10% before death. During this acute phase, *A. marginale* can be detected within the erythrocytes by microscopic examination of blood smears stained with Wright's, new methylene blue, or Giemsa stain. The inclusion is composed of a small morula of two to eight individual organisms, and over 5%, up to 20% to 70%, of the erythrocytes may be infected. Later, after several days of anemia, the percentage of infected erythrocytes decreases dramatically, and evidence of RBC regeneration can be detected. There is anisocytosis, basophilic stippling, poikilocytosis, polychromatophilia, and reticulocytosis.

After recovery from acute disease, cattle and sheep remain persistently infected, with 0.000001% to 0.1% of erythrocytes being infected. These extremely low levels cannot be reliably detected by microscopic examination, and persistently infected animals, which serve as reservoirs for transmission, need to be detected serologically. Serologic diagnosis is most often accomplished through competitive enzyme-linked immunosorbent assay (cELISA),* which provides both high specificity and, unlike the complement fixation test, high sensitivity in detection of persistently infected carrier cattle.[113,114] The cELISA, approved as an official test by the U.S. Department of Agriculture (USDA) and the Office of International Epizootics (OIE), is conducted by most, if not all, state diagnostic laboratories. Currently, negative status with the cELISA is required for importation of live cattle into Canada. Although cattle will seroconvert by cELISA during acute infection, serology generally is of minimal utility in diagnosis of acute anaplasmosis.

1155 1156

* VMRD Inc., Pullman, Wash.

37.6.5 Pathophysiology

Anaplasma species are naturally transmitted by Ixodidae ticks, most often the genera *Dermacentor* in the mainland United States and *Rhipicephalus* (including tick species previously classified in *Boophilus*) in tropical and subtropical regions worldwide. Although there is strong epidemiologic evidence of transmission by hematophagous flies, under experimental conditions this is very inefficient,[115] and thus the field conditions that allow transmission remain poorly understood. In addition, direct iatrogenic transfer of infected blood (contaminated needles; dehorning, castrating, hormone-implanting, or ear-tagging instruments) can result in transmission. After transmission, sequential rounds of bacterial invasion of mature erythrocytes, replication, and egress result in a progressively increasing, cell-associated bacteremia, with a doubling time of

approximately 24 hours. Clinical signs appear when greater than 1% of erythrocytes are infected and the severity roughly correlates with the percentage of infected erythrocytes. Anemia is at least partly caused by splenic and hepatic macrophage-mediated phagocytosis of both infected and uninfected erythrocytes. This appears to reflect both induction of autoantibodies against the RBC surface and induction of acute-phase reactants, including complement activation, during high-level rickettsemia. The regenerative response to anemia can be vigorous and does not appear to be suppressed by the infection.

Protective immunity appears to require induction of both antibody against the outer membrane proteins and macrophage activation for enhanced phagocytosis and bacterial killing.[116] Although the immune response controls the acute phase of infection, organisms are not completely cleared from the blood because of the emergence of antigenic variants.[117] These variants are responsible for persistent infection, characterized by recurring waves of bacteremia that reflect sequential emergence and then immune control of antigenically variant organisms.

37.6.6 Epidemiology

A. marginale is the most prevalent of the tick-borne infections of cattle worldwide and remains a serious constraint to livestock production in tropical and subtropical regions. However, anaplasmosis is also a significant problem in temperate regions. In the United States, infection is endemic in much of the West and occurs episodically in many historically nonendemic regions; anaplasmosis has been detected in at least 40 states. Canada is considered to be free of endemic anaplasmosis. Endemic regions are maintained by the prevalence of both competent arthropod vectors and persistently infected carrier cattle. These carrier cattle, which are typically asymptomatic, are efficient reservoirs for tick-borne transmission.[115,118] Vector activity varies by region, but outbreaks of anaplasmosis generally occur most frequently in the late spring and summer, when arthropod activity is highest. However, it should be emphasized that the determinants of tick-borne and fly-borne transmission are not well understood, and transmission is often unpredictable. In contrast, iatrogenic transmission can occur at any time and can be controlled by avoiding blood contamination during veterinary medical procedures. Although wild ruminants (e.g., deer, elk, bison) rarely have clinical disease and generally are asymptomatic, persistently infected carriers, their overall importance in the epidemiology of infection is unclear. Currently, wild ruminants are thought to play at most only a minor role in natural transmission.

37.6.7 Pathology

At necropsy, there are no pathognomonic lesions for the diagnosis of anaplasmosis. In acute anaplasmosis the blood is thin and watery and fails to clot readily. Mucous membranes, subcutaneous tissues, and skeletal musculature are pale (anemic pallor). In later stages of acute disease, however, the same tissues exhibit varying degrees of icterus. Splenomegaly is a consistent finding; hepatomegaly and distention of the gallbladder are common but seen less often. Urine is deep yellow, but neither hemoglobinuria nor hematuria occurs. The absence of hemoglobinuria helps differentiate anaplasmosis from other hemolytic diseases (babesiosis, bacillary hemoglobinuria, leptospirosis, onion toxicity, copper poisoning in sheep). Occasionally, petechiae may be found in the subepicardium, subendocardium, and other serous membranes. Detection of *A. marginale*—infected erythrocytes within capillaries of Giemsa-stained histologic sections can be used to confirm a diagnosis of anaplasmosis.

37.6.8 Treatment

Tetracyclines are the antibiotic of choice for treating acute disease, and resistance has not been reported. In acute anaplasmosis, oxytetracycline at 11 mg/kg IV every 24 hours for 3 to 5 days is effective. One to two administrations of long-acting oxytetracycline at 20 mg/kg IM at 72-hour intervals is also an effective treatment. In addition to antibiotic therapy, supportive therapy is important. If the PCV is 12% or lower, whole-blood transfusion may be indicated to prevent death and shorten the convalescent period; 4 to 8 L of whole blood is usually administered to an adult animal. A PCV of 8% or lower indicates an unfavorable prognosis, and death often occurs despite appropriate antibiotic and supportive therapy. Importantly, the oxytetracycline regimen used to treat acute anaplasmosis is not effective in completely clearing the animal of the organism, and recovered animals become persistently infected carriers. Although prior studies showed that long-acting oxytetracycline at 20 mg/kg every 3 days for four successive treatments resulted in clearance, more recent studies using this regimen and variations of this regimen have indicated that clearance is not achieved.[119] If required for exportation, clearance should be confirmed by conversion to seronegative status.

37.6.9 Prevention and Control

Control measures vary depending on the geographic region and type of livestock production system. In endemic regions with high transmission rates, such as those in tropical countries, beef cattle are often allowed to become naturally infected at a young age and remain asymptomatic carriers with minimal risk of later acute disease. In regions with lower transmission rates, live blood-based vaccines may be used to ensure infection of cattle at a young age. This is exemplified by the use of trivalent *(A. marginale, Babesia bovis, Babesia bigemina)* live vaccine in Australia. Similarly, live vaccines based on *A. centrale* or weakly virulent strains of *A. marginale* are typically used in Africa, Asia, and Central and South America. However, these are not licensed for use in the United States, largely because of the risk of transmitting known or newly emergent pathogens contaminating the blood-based vaccine. The exception to this is the licensing of a live vaccine* for use in California. Importantly, these live vaccines should only be used in young animals and are contraindicated for use in older and especially pregnant animals. Killed vaccines are less efficacious and require multiple immunizations, but these can induce at least partial protection against severe morbidity and mortality. Unfortunately, none of the federally licensed killed vaccines previously marketed in the United States are currently available. However, an experimental killed vaccine* has been licensed for use in 14 states and Puerto Rico.

1156

1157

In the absence of immunoprophylaxis, anaplasmosis is usually controlled by preventing transmission. Although it is difficult to prevent completely the contact of ticks and biting flies with cattle grazing on open ranges or farm pastures, strategic use of acaricides and insecticides can reduce transmission during periods of high vector activity. Periodic spraying for tick control and the use of insecticide-impregnated ear tags or insecticide dust bags for biting-fly control are cost-effective, not only for control of anaplasmosis but also for control of pinkeye and for directly reducing irritation and increasing weight gain. Because blood-contaminated instruments and needles can mechanically transmit infection, appropriate sanitary measures should be implemented when injections or surgical procedures are performed.

Maintenance of an *A. marginale*–free herd in nonendemic areas can be accomplished by quarantine and serologic screening of all additions using the USDA-approved cELISA. Within endemic regions, however, this requires extreme vigilance in screening and prevention of both direct contact and sharing pasture with other domestic and wild ruminants, which may result in vector-borne transmission. The risk of maintaining a fully susceptible herd within an endemic region should not be taken lightly.

Table 37-1 *Babesia* Species (Babesiosis)

Organism	Livestock Affected	Principal Geographic Distribution	Morphology of Organism	Tick Vectors
B. bigemina (B. bovis)	Cattle	Americas, Europe, Africa, Australia, Middle East	4.5 × 2.5 µm (large, round, and pyriform; acute angle)	*Boophilus annulatus, B. decoloratus, B. microplus*
B bovis (B. berbera, B. argentina)	Cattle	Americas, Europe, Russia, Africa, Asia, Australia	2.4 × 1.5 µm (small and more rounded; obtuse angle)	*B. annulatus, B. microplus, Ixodes* species (?)
B. divergens	Cattle	Europe	1.5 × l.4 µm (small, narrow and obtuse angle)	*Ixodes ricinus*
B. major	Cattle	Europe, Russia, North Africa, Middle East	2.6 × 1.5 µm (similar to *B. bigemina,* but smaller)	*Haemaphysalis punctata*
B. jakimovi	Cattle	Asia	2-4.6 × 1.5-2.1 µm (large, round, and pyriform)	*I. ricinus*
B. ovata	Cattle	Japan	4.5 × 2.5 µm (large, round, and pyriform)	*Haemaphysalis longicornis*
B. caballi	Horses	Americas, Europe, Russia, Asia, Africa, Middle East	3 × 2 µm (large, pyriform; acute angle)	*Dermacentor, Hyalomma,* and *Rhipicephalus* species
Theileria equi (B. equi)	Horses	Americas, Europe, Russia, Asia, Africa, Middle East	1-2 µm (small and rounded; Maltese cross is characteristic)	*Dermacentor, Hyalomma,* and *Rhipicephalus* species
B. motasi	Sheep and goats	Europe, Russia, Asia, Middle East	3 × 2 µm (large, pyriform; acute angle)	*D. silvarum* (?), *Haemaphysalis* species, *R. Bursa*
B. ovis	Sheep and goats	Europe, Russia, Asia, Middle East	1.5 × 1 µm (small and more rounded; obtuse)	*I. ricinus* (?), *R. bursa, D. reticulatis* (?)
B. trautmanni	Swine	Europe, Africa, Russia	3.5 × 2 µm (large, narrow, and long; acute angle)	*R. sanguineus* (?), *Dermacentor* species (?), *Boophilus* species, *Hyalomma* species (?)

B. perroncitoi	Swine	Europe, Africa, Asia	0.7-2 µm (small and more rounded)	Vectors unknown

37.7 Babesiosis

JERRY L. ZAUGG

Babesiosis is a tick-borne intraerythrocytic disease of domestic and wild mammals and humans caused by protozoan parasites of the genera *Babesia* and *Theileria*. The acute disease is characterized by fever, hemolytic anemia, icterus, hemoglobinuria, and death. Although both morphologic and serologic differentiation is needed for specific identification of the various disease-producing species, all can be categorized as being either "large" or "small" in size. Table 37-1 presents common *Babesia* species (and *Theileria equi*), their usual biologic vectors, and livestock hosts. Babesiosis has a wide geographic distribution, particularly in the tropics and subtropics, largely related to the distribution of vector ticks. Of the different diseases, the economically most important infections of livestock are those of cattle and horses.

37.7.1 BABESIOSIS IN THE BOVINE

JERRY L. ZAUGG

37.7.1.1 Etiology

Known variously by such names as bovine babesiosis, piroplasmosis, Texas fever, redwater, tick fever, and tristeza, the disease may be caused by at least six *Babesia* species (see Table 37-1). Animals other than cattle known to be susceptible to agents of bovine babesiosis include white-tailed deer, American bison, water buffalo, reindeer, and African buffalo. Infections in these other animals are nominal, and except under unusual conditions, such hosts are probably not significant reservoirs.

1157

1158

Of greatest concern in the Western Hemisphere are the species *B. bigemina* and *B. bovis. Babesia bigemina* is a large species characteristically appearing within mature erythrocytes as nonpigmented, paired, pear-shaped bodies joined at an acute angle. Irregularly shaped, round, or amoeboid forms are also seen. *Babesia bovis* is a small, pleomorphic species often identified as a single round body or as paired, pear-shaped bodies joined at an obtuse angle within mature erythrocytes. Of the two species, *B. bovis* is usually considered the most virulent.

Natural transmission of both species occurs primarily by the feeding of various stages of the one-host ticks of the genus *Boophilus*. Ticks are most often infected transovarially (vertically). The female tick becomes infected by the ingestion of parasites during engorgement. After it drops off the host, the babesial organisms reproduce within the tick's tissues. Some of the reproducing organisms are incorporated within developing tick embryos, and the disease agents are transmitted to new vertebrate hosts by the feeding of ensuing tick larvae, nymphs, or adults. Larval ticks may transmit *B. bovis*, but *B. bigemina* is not transmitted until the

larvae have molted into the nymphal or adult stages. Both *Babesia* species may also be transmitted iatrogenically through blood-contaminated fomites, as described under Anaplasmosis.

37.7.1.2

Clinical Signs

Clinical signs manifest 2 to 3 weeks after tick infestation. The incubation period after blood inoculation may be less than 5 days to more than 3 weeks, depending on the volume of inoculum. Clinical signs of fever (40° C to 42° C, 104° F to 107.6° F), depression, icterus, anorexia, tachycardia, tachypnea, anemia, hemoglobinemia, hemoglobinuria, abortion, and death are seen. Anemia is caused by intravascular destruction of erythrocytes by escaping merozoites after intraerythrocytic reproduction of the babesias by binary fission. In addition, the osmotic fragility of the whole-erythrocyte population increases terminally, such that massive lysis occurs, even though the parasitemia may be less than 1%.[120] Additionally, as also seen with anaplasmosis, an autoimmune condition may result in which the spleen removes damaged and apparently healthy erythrocytes from circulation. Thus, the degree of anemia may exceed that expected with a low parasitemia. The anemia may occur rapidly, with 75% or more of the erythrocytes destroyed in a few days. The exit of *B. bigemina* and *B. bovis* parasites from infected erythrocytes releases two or more parasite-associated proteolytic enzymes into the plasma. These enzymes and other parasite metabolic products are believed to interact with blood components and are responsible for such clinical signs as metabolic acidosis and anoxia. Tachycardia may be dramatic and the heartbeat pronounced.

Cerebral babesiosis, characterized by hyperexcitability, convulsions, opisthotonos, coma, and death, may be observed in cattle infected with either *B. bigemina* or *B. bovis*, but especially with the latter. Central nervous system (CNS) signs are caused by brain anoxia resulting from severe anemia and erythrocyte blockage of cerebral capillaries.

Death is caused by a shocklike syndrome associated with the accumulation of toxins, release of vasoactive substances, and anemic anoxia. Most cases with cerebral involvement are fatal; however, mortality is extremely variable, depending on *Babesia* species involved, susceptibility of the host, and management and environmental stress factors. Many cattle that survive the acute phase recover but become chronic carriers. Other survivors often experience episodes of recrudescence, eventually succumbing to the disease, or they may die as a result of secondary infections contracted during their debilitated state.

Cattle of all breeds are susceptible to babesiosis. However, *Bos indicus* breeds exhibit a definite degree of resistance to both *Babesia* species and the tick vectors.[121] Calves possess a natural immunity to babesiosis. Such immunity was believed to be reinforced by colostral antibodies for calves born to previously infected dams.[122] However, erythrocytes of young bovines may contain factor(s) independent of antibody that provide an innate resistance to severe babesiosis.[123] Thus, calves infected up to the age of 9 months experience a minimum reaction to the disease, becoming asymptomatic carriers. Carriers remain resistant to clinical disease for at least 4 years.[124] The carrier state can be overcome, however, by such stressors as calving, malnutrition, and concurrent disease.[125]

37.7.1.3

Clinical Pathology

Clinical signs observed in cattle in enzootic areas with *Boophilus* ticks may provide sufficient data for a presumptive diagnosis. Other conditions that may exhibit similar signs as babesiosis are anaplasmosis, trypanosomiasis, theileriosis, leptospirosis, chronic copper toxicity, and bacillary hemoglobinuria. The cerebral signs may be confused with rabies and other encephalitides. A positive diagnosis requires

identification of the *Babesia* species on Giemsa-stained thin blood smears, positive serologic tests, or inoculation of splenectomized calves with infective blood. In acute infection, *Babesia* species can usually be detected in smears made from peripheral blood. In chronic cases, numbers of parasitized erythrocytes diminish, becoming so sparse as to make detection difficult. This is especially true with *B. bovis,* which shows a marked tendency to accumulate in capillaries, particularly those of the brain. *B. bovis* may favor capillaries in the brain and kidney because the major energy-producing pathway of *Babesia* appears to be anaerobic glycolysis. The blockage of cerebral and renal capillaries by parasitized erythrocytes results in an anaerobic condition that enables the parasites to absorb preformed substrates by pinocytosis and diffusion through their surface membranes. PCV values drop rapidly from a normal of 35% to below 10% in less than a week after onset of clinical signs.[126] Serum potassium levels decrease in some infected animals, whereas urine potassium levels increase in almost all cases.[127]

Specific anti-*Babesia* antibodies are detectable in cattle sera less than 7 days after infection.[128] Such antibodies also exist for at least 252 days after the disappearance of detectable parasites.[129] The complement fixation (CF) and indirect fluorescent antibody (IFA) tests are the most widely used.[128] The CF test follows the same basic procedure used in anaplasmosis CF testing[130] with a *Babesia* antigen.[131] The test is effective, but approximately 100 days after infection, the CF antibodies drop below a reliable diagnostic level.[128] The IFA test uses the whole intraerythrocytic parasite as antigen rather than an extract and commercially prepared rabbit antibovine γ-globulin conjugated to fluorescein.[128] Other serologic tests include gel precipitation,[132] latex particle agglutination,[133] rapid card agglutination,[134] and enzyme-labeling immunoassay (EIA).[135] The immunologic assays, however, are indirect methods and do not detect the causal organisms in samples obtained from a suspected infected animal. Recombinant DNA techniques using selected clones containing inserts of *Babesia* genomic DNA sequences are now available to be used as specific, highly sensitive DNA or RNA probes to detect the presence of the hemoparasite DNA in an infected animal or a tick vector.[136]

37.7.1.4

Necropsy Findings

Postmortem findings in cattle that die peracutely are characteristic of an acute hemolytic crisis. Such findings include a generalized pallor or icterus throughout the carcass; an enlarged icteric liver; gallbladder distended with thick, dark-green bile; and a greatly enlarged, dark, soft spleen. Hydropericardium and subepicardial/subendocardial petechiation may be seen. The blood is thin and watery. The urinary bladder is frequently distended with dark-red urine. There may be subserosal ecchymotic hemorrhages in abomasal and intestinal mucosa, and the lymph nodes are edematous. The carcass of an animal that dies after a prolonged illness is generally emaciated and icteric. The intermuscular fascia is also edematous. The kidneys are pale and edematous, and the bladder may contain pink-tinged or normal urine. The liver is enlarged and jaundiced, and the bile may contain flakes of semisolid material.

1158 1159

37.7.1.5

Treatment and Prognosis

After the onset of hemoglobinuria or cerebral signs, the prognosis is poor. Acute cases with PCV values above 12% usually respond well to treatment. The prognosis decreases for cases with PCV values below 10%. Successful treatment depends on early diagnosis and prompt therapy. In addition to specific treatment, supportive therapy such as blood transfusions (4 L of whole blood per 250 kg of body weight), fluids, hematinics, and prophylactic antibiotics are important. However, wild, excitable cattle may best be left alone.

With severe hemolytic anemias, any exertion associated with restraint and treatment may precipitate an anoxic crisis.

The small *Babesia* species are more resistant to chemotherapy and may require increased dosages or additional treatments. The most frequently used, effective, and relatively less toxic specific babesiacides are diminazine aceturate* at 3 to 5 mg/kg; phenamidine diisethionate† at 8 to 13 mg/kg; imidocarb dipropionate‡ at 1 to 3 mg/kg; and amicarbalide diisethionate§ at 5 to 10 mg/kg.[137] Generally, treated cattle become chronic carriers and are resistant to further clinical episodes of the disease. However, treatment of *B. bigemina* may be so effective that sterilization occurs, eventually leaving the animal susceptible to reinfection. Imidocarb has both therapeutic and prophylactic activities. In enzootic areas, its use prevents clinical infection for as long as 2 months but at the same time allows mild, subclinical infections to occur, resulting in premunition immunity.[138,139]

37.7.1.6

Prevention and Control

Eradication of *Boophilus* tick vectors has provided effective control in the United States. Other such projects attempted elsewhere have not been successful because of such diverse reasons as tick resistance to acaricides; ability of some ticks to infest alternate, nonbovine hosts; failure to obtain 100% cooperation of cattle producers; and lack of financial resources to sustain a prolonged program.

Most procedures aimed at reducing tick infestations (acaricide applications [on host or over environment], controlled range burning, cultivation, prolonged pasture rest, use of repellents) are beneficial. Care should be taken to prevent accidental transfer of blood from one animal to another in routine surgery (e.g., dehorning, castration, ear marking, hormone implantation) and vaccination procedures.

The most common form of immunization consists of inoculating live organisms (virulent or attenuated) into susceptible calves to induce a state of premunition. Inoculation of older animals is followed by nonsterilizing chemotherapy as needed to modify clinical effects.[140] Although a premunition approach is useful in endemic areas, it is less desirable in areas with low infection rates because the premunized carriers provide a large reservoir of infection. Some killed adjuvant vaccines have proved successful in limited trials.[141] In vitro cell cultivation techniques have yielded highly immunogenic soluble antigens of *B. bovis*.[142] Subunit vaccines derived from monoclonal technologies were proved effective in protecting against severe clinical disease.[143] The monoclonal antibodies apparently inhibit merozoite invasion of the erythrocytes. Vaccines of such noninfectious material generally do not prevent disease, but they do moderate the effects of infection and do not directly produce carriers.

37.7.2 BABESIOSIS IN THE HORSE

37.7.2.1 Etiology

Babesiosis/theileriosis of equids (piroplasmosis) is a febrile, tick-borne disease caused by *Babesia caballi* and *Theileria equi*. Until recently, *T. equi* was known as *Babesia equi*. However, because the organism more closely resembles members of the genus *Theileria* with its exoerythrocytic (lymphocytic) stages within the vertebrate host, with development of microschizonts and macroschizonts, *B. equi* is now classified as *Theileria equi*[144] (see Table 37-1). *Babesia caballi* is a large species resembling *Babesia bigemina,* which affects cattle. Although *T. equi* is not a member of the genus *Babesia*, for practical purposes it is still considered a "small" parasite, similar to *B. bovis* on stained thin blood smears. However, a unique characteristic of *T. equi* is that the intraerythrocytic parasites divide into four cells to form a Maltese cross.[145]

Equine piroplasmosis is widely distributed throughout the tropics and subtropics and to a lesser extent in temperature regions. The distribution roughly corresponds to those of the tick vectors. Both species are naturally transmitted by ticks of the genera *Dermacentor, Hyalomma,* and *Rhipicephalus. B. caballi* is passed transovarially (vertically) from one tick generation to the next. Transmission of *T. equi* apparently occurs only transstadially (horizontally); one tick stage (larvae or nymphs) becomes infected, and the disease agent is passed to the next vertebrate host in the next tick stage (nymph or adult). Because of the widespread prevalence of potential tick vectors in the United States (*Dermacentor albipictus, D. iteus,* and *D. variablis*), it is unknown why equine piroplasmosis is not a problem in the United States.

37.7.2.2 Clinical Signs

All equids apparently are susceptible to both parasite species. The zebra in Africa is naturally infected with *T. equi* but not with *B. caballi*. Once infected, survivors remain chronic carriers. *T. equi* can be transmitted transplacentally. Clinical features after an incubation period of 5 to 28 days include fever (39° C to 42° C; 102° F to 107.6° F), hemolytic anemia, jaundice, hemoglobinuria, and death. Generalized signs of depression, anorexia, incoordination, lacrimation, mucous nasal discharge, swelling of the eyelids, and frequent lying down are seen. *T. equi* is considered the most pathogenic of the two species and is responsible for a greater incidence of hemoglobinuria and death. *B. caballi* causes a more persistent fever and anemia. Differential diagnoses include equine monocytic ehrlichiosis, equine infectious anemia, liver failure with hemolytic anemia, and other hemolytic anemias of the horse.

37.7.2.3 Clinical Pathology

A fever associated with anemia, jaundice, and hemoglobinuria, with the detection of parasite-infected erythrocytes in Geimsa-stained blood smears, is diagnostic. A significant increase in relative and absolute numbers of monocytes and absence of eosinophils may be observed in horses infected with *T. equi*. Hemoglobinuria is rare in animals infected with *B. caballi,* but urine is often dark yellow. The most frequently used serologic tests are CF and IFA tests. Blood from spleen-intact horses can become CF positive within 14 days after parasite exposure. There is also a cELISA test for *T. equi* and a polymerase chain reaction (PCR) test for both equine diseases. Further, as with the bovine infections, both *B. caballi* and *T. equi* infections can be specifically detected with nucleic acid probes.[136]

1159 1160

37.7.2.4 Necropsy Findings

Postmortem features are similar to those seen in bovine babesiosis, but jaundice is even more prominent throughout the carcass. There is excessive fluid in the body cavities, especially the pericardial sac. Pulmonary edema is evident. The liver is swollen, and hepatic vessels contain large, yellowish clots. The spleen in enlarged with rounded edges.

37.7.2.5 Treatment and Prognosis

Generally, both *B. caballi* and *T. equi* respond to the same babesiacidal drugs used to treat bovine babesiosis, but *T. equi* is more refractory to treatment than *B. caballi*. If diagnosed early and treated promptly, recovery is the rule. The drug of choice for eliminating the carrier state of infected animals is imidocarb; at 2.2 mg/kg twice in 24 hours, imidocarb is effective against *B. caballi;* 4 mg/kg four times over 72 hours is effective against *T. equi* of Eastern Hemisphere origin.[137] However, donkeys receiving similar treatment died from drug toxicosis.[121] The higher doses of imidocarb often produce transient side effects in horses similar to signs seen in colic. To date, attempts to eliminate consistently the carrier state of *T. equi* of Eastern European origin have been unsuccessful.[146] However, as proposed in 1993,[147] irregular chemical sterilization success has been obtained with concurrent IV buparvaquone* at 4 mg/kg and IM imidocarb at 4 mg/kg.

* Butalex, Coopers Animal Health Limited, Hertfordshire, United Kingdom.

37.7.2.6 Prevention and Control

Control of the tick infestations does much to reduce disease incidence, as does care to prevent blood transfer during such routine surgical procedures as castration. No vaccines effectively prevent equine babesiosis. Premunition (as used in bovine babesiosis) is of limited value in some enzootic areas, but it is not widely practiced because early treatment without sterilization is effective, and the resulting chronic carriers resist further disease challenge.

37.8 Hemobartonellosis (Eperythrozoonosis)

GARY P. CARLSON

Haemobartonella bovis is an epicellular organism that is closely associated with the surface of erythrocytes. It may appear as a rod shape, an ovoid, or in chains with conventional stains. Hemobartonellosis is primarily of academic interest in North America because it is rarely a cause of anemia.[148] The organism has been found in association with other rickettsial diseases and has been experimentally transmitted in splenectomized calves. The agent may be visualized as delicate ovoid, rod, or dumbbell forms arranged in chains or tight groups or randomly distributed epicellularly throughout appropriately stained blood smears.

37.8.1 EPERYTHROZOONOSIS IN CATTLE

The causal agent is *Eperythrozoon wenyoni (Mycoplasma wenyoni)*. Infection is usually latent, producing no clinical signs in normal cattle, but it may become apparent in animals that have been severely stressed by some other systemic disease. The disease can be produced experimentally if infected blood is administered to

splenectomized calves. Even under experimental circumstances, clinical signs consist of mild depression, fever, and modest anemia. The disease in cattle is of little clinical consequence, except for the potential for confusion should the organism be seen on stained blood films. Occasionally, cattle may have swollen and tender teats and legs.[148]

37.8.2 EPERYTHROZOONOSIS IN SHEEP AND GOATS

The causal organism in sheep and goats is *Mycoplasma ovis (Eperythrozoon ovis)*, which appears to be very similar morphologically and serologically to the species found in cattle. The disease can produce more prominent clinical signs in sheep, with profound depression, anemia, and significant death losses in young lambs.[149] Erythrocyte destruction is thought to be caused by intravascular hemolysis and erythrophagocytosis.

37.9 Theileriasis

GARY P. CARLSON

Theileriasis is caused by small hemoparasite of the genus *Theileria* that infects lymphocytes and erythrocytes of ruminants and is most common in tropical and subtropical climates. The organism is spread by bloodsucking arthropods, particularly ticks of the Ixodidae family. *Theileria parva* is the cause of East Coast fever, a highly fatal disease of cattle in Africa. Other members of the genus *Theileria (T. annulata, T. mutans, T. hirci*, and *T. ovis*) tend to be less pathogenic and produce diseases with a wider geographic distribution.[149] *T. cervi* has been seen in North American deer. *T. mutans* has been seen in erythrocytes of both cattle and deer in North America. Theileriosis caused by an agent indistinguishable from *T. buffeli* has been described in cattle from Texas and North Carolina with parasitemia, but clinical signs were not reported.[150] Recently, *T. buffeli* was reported as the cause of a hemolytic anemia in a 6-month-old Simmental calf.[151] There was serologic evidence of a high herd prevalence of *Theileria* infection, and the agent was transmitted to splenectomized calves, which developed mild anemia. The organism produces a brief illness characterized by mild fever, anorexia, and modest anemia, followed by rapid recovery.

37.10 Trypanosomiasis

GARY P. CARLSON

Trypanosomes are flagellated protozoal organisms that can produce a variety of serious diseases of humans and animals, although many are nonpathogenic. Nagana, a disease of cattle in Africa, is caused by *Trypanosoma congolensi. Trypanosoma evansi* is the cause of surra, a disease of cattle in India, and *Trypanosoma equiperdium* produces dourine in horses. In North America, *Trypanosoma theileri (Trypanosoma americanum)* is the only agent reported and is principally of academic interest because it is relatively nonpathogenic. The organism is occasionally seen free in the plasma in small numbers on stained blood films from cattle as a large, flagellated protozoan with an undulating membrane.[149] The organism is best visualized in buffy coat smears, which tend to concentrate it. *T. theileri* rarely produces clinical signs, but occasionally a fulminating parasitemia may develop, resulting in fever, depression, and decreased milk production.

37.11 Leptospirosis

GARY P. CARLSON

Leptospira infections produce disease in several species, including cattle, sheep, swine, horses, dogs, and humans, but the acute hemolytic syndrome associated with these infections is seen most often in calves and lambs. *Leptospira interrogans* serovars *pomona* and *icterohaemorrhagiae* are the serotypes usually involved in the hemolytic syndrome. Clinical signs of the hemolytic syndrome vary but generally include fever, lethargy, icterus, anemia, and petechial hemorrhages. The anemia results, at least in part, from immune-mediated mechanisms. Cold-reacting immunoglobulin M (IgM) antibodies have been implicated in the hemolytic anemia seen in lambs. The degree of anemia is variable but can be severe, with evidence of erythropoietic response apparent in the peripheral blood within 4 to 7 days. A moderate leukocytosis and elevation in plasma fibrinogen are often associated with the hemolytic anemia. The diagnosis is generally made on demonstration of the organism in the urine, PCR, and an increase in serum antibody titer. Discussion of leptospirosis as a reproductive, renal, and ocular problem can be found in other chapters.

1160
1161

37.12 Equine Leptospirosis

MONICA ALEMAN

Leptospirosis is a bacterial zoonotic disease that is prevalent worldwide.[152] The organism can be readily transmitted between mammalian species (cattle, pigs, horses, dogs, and humans) through infected urine, body fluids, and contaminated soil or water.[153] In horses from North America, infections are primarily caused by *Leptospira interrogans* serovar *pomona kennewicki*.[154] There are various maintenance hosts for this serovar, with the skunk being the most common host. *Leptospira bratislava* has been considered the host-adapted serovar of the horse, although this has been controversial. Some researchers believe this serovar is also pathogenic to the horse, and when the horse is infected, the organism can be shed indefinitely in urine and possibly the reproductive tract.[154]

Leptospira pomona can cause uveitis, placentitis, abortion, stillbirth, renal disease, and hemolysis. Clinical signs include fever, jaundice, anorexia, and lethargy. Leptospirosis is a sporadic cause of abortions, although in endemic areas it may account for 13% of bacterial abortions.[155] In general, abortions occur during late-term gestation. The organism can be found in the placenta, umbilical cord, kidney, and liver of the aborted fetus. *L. pomona* can be shed in urine for up to 14 weeks after infection. *Leptospira grippotyphosa* and *L. hardjo* are serovars also known to cause equine abortions.[154]

Renal disease, tubulointerstitial nephritis, pyuria, and rarely acute renal failure have been reported in horses with leptospirosis. More often, two ocular disorders appear to be associated with *L. pomona* infection in horses: *equine recurrent uveitis* (ERU) and *immune-mediated keratitis*. The immune-mediated response is postulated to result from the cross-reaction between leptospiral antigens and uveal tissue, cornea, lens, vitreous body, and retina.[156] Recent reports have confirmed the presence of live *Leptospira* in the uveal tissue of horses with uveitis through isolation of the organism, positive PCR, or high antibody titer in the aqueous humor.[156]

37.12.1 Diagnosis

Diagnosis of leptospirosis can be challenging because of variable serologic results. Microscopic agglutination titer (MAT) in serum and fluorescent antibody titer (FAT) in infected tissues have been routinely used for diagnosis. The sensitivity and specificity of FAT in tissues of aborted fetuses are almost 100%.[155] In cases of uveitis, high antibody titers in aqueous humor may be found despite variable serum titers, suggesting local

antigenic stimulation.[156] Serum titers of 1:6400 are considered significant and consistent with infection.[157] Serum titers of 1:3200 that are stable for 2 to 3 weeks are not considered significant. Rising titers after 2 to 3 weeks are considered significant, and the patient should be isolated and treated. Other diagnostic modalities are PCR, histology, and bacterial isolation. Recently, Divers[155] isolated genes of two surface proteins of *L. pomona* (immunoglobulin-like proteins A and B) that are expressed only during active infection. These proteins may improve the diagnosis and development of a protective vaccine for leptospirosis.

37.12.2 Treatment

Treatment for leptospirosis has been advocated with ampicillin, amoxicillin, procaine penicillin (22,000 IU/kg IM every 12 hours), oxytetracycline (5 to 10 mg/kg IV every 24 hours, slow in fluids not containing calcium), or doxycycline (7 to 10 mg/kg PO every 12 hours) for 7 days. The inflammatory response in horses with ERU and immune-mediated keratitis has been managed with corticosteroids and cyclosporine, but this may provide only temporary relief. Affected horses tend to develop ocular complications (e.g., cataracts, glaucoma, blindness, intractable pain) that may result in enucleation. The inability to cure many cases of ERU may be caused by the lack of treatment for the possibly active infection. Therefore, treatment should be directed toward controlling the ocular inflammatory response and ongoing infection, if indicated. Systemic antimicrobial therapy may not be successful in ERU cases resulting from an intact blood ocular barrier despite being inflamed.[155]

37.12.3 Prevention

Prevention must be aimed at controlling exposure to shedding hosts, infected animals, and contaminated fomites. Thorough cleaning and disinfection of contaminated areas and proper disposal of infected material are essential measures to minimize exposure. Pregnant mares should be isolated from other animals because bacterial shedding may last several weeks. If abortions occur in endemic areas, it is recommended to test horses for leptospiral antibodies and isolate those horses with a serum titer of 1:6400 or higher.[157] Also, horses with a negative or low titer should be retested in 2 to 3 weeks. Horses with rising titers should be isolated. Attempts to decrease shedding in horses with oxytetracycline, penicillin G, and streptomycin have not been effective. Vaccination is sometimes performed on farms with endemic abortions or high rates of uveitis.[155]

37.13 Bacillary Hemoglobinuria (Redwater)

GARY P. CARLSON

Bacillary hemoglobinuria is an acute hemolytic disorder caused by *Clostridium haemolyticum* (*Clostridium novyi* type D). Also known as “Nevada redwater,” it has been reported as a naturally occurring disease in cattle and has been experimentally produced in sheep. Clinical signs develop rapidly, and death losses are often seen. Affected animals may manifest severe depression, anorexia, fever, hemoglobinemia, and hemoglobinuria. The disease is endemic in certain poorly drained areas of the western United States and is caused by ingestion of infectious spores. The organism finds a favorable environment for development in areas of preexisting liver damage, most often produced by migrating liver flukes. The hemolytic syndrome results from toxins elaborated by the organism, which also produce a characteristic focal liver lesion. The anemia produced may be marked, and both icterus and evidence of erythropoietic response may be seen in animals that survive for more than a few days. (See Chapter 33.)

37.14 Equine Infectious Anemia

BRETT SPONSELLER

Equine infectious anemia virus (EIAV) is an RNA virus, a member of the Retroviridae family, belonging to the *Lentivirus* genus. It has a structure and genome organization similar to other animal and human lentiviruses. Lentiviruses use virally encoded *reverse transcriptase* to convert the RNA genome to a DNA intermediate that is integrated into the host's genome by another virally encoded enzyme, *integrase*. The integrated DNA intermediate, or provirus, usurps the host cell to replicate its genome, manufacture viral proteins, and assemble the virally encoded proteins into virions, which subsequently bud from the cell. Thus, infection by a lentivirus results in a lifelong, persistent infection. EIAV causes the disease, equine infectious anemia (EIA), first described in 1843 by Lignée.[158] In 1904, Carré and Vallée[159] determined that EIA was associated with a filterable agent, making it the first animal disease determined to be caused by a virus.

37.14.1 Serosurveillance and Detection

EIA is a USDA-regulated disease. In 2003 the USDA estimated that serosurveillance of almost 2 million samples cost U.S. horse owners more than $48 million. USDA-accredited laboratories use a testing scheme that detects the presence of serum antibody to the virus. The Coggins' test, developed by Dr. Leroy Coggins in 1970, provided the first efficient serologic test for detection of EIAV-infected animals; it remains a USDA-accepted test.[160,161] In addition, four ELISAs are licensed tests, one of which is a competitive ELISA (cELISA). These ELISAs detect antibody directed at the transmembrane glycoprotein (gp45) and the p26 antigen.[162] All areas in the United States, Canada, and Mexico accept either the Coggins' test or one of the licensed ELISAs when testing for EIA is required for entry. Equids that cross state lines or that attend many equestrian events are required to be seronegative for EIA; however, the required period of seronegativity between tests varies according to the state. No tests are currently approved by the USDA for diagnosis of EIA based on detection of viral nucleic acid.

Serosurveillance can lead to the detection of horses that are infected with EIAV but that otherwise appear healthy. Indeed, most infected horses are inapparent carriers. However, blood transferred from an inapparent carrier to another horse, through instruments (e.g., needles, nasogastric tubes, dental equipment), blood products, or insect vectors (primarily tabanids), can lead to infection with a fatal outcome.

37.14.2 Clinical Findings

The clinical form of EIA is characterized by three defined, temporal stages of disease: acute, chronic, and inapparent. The *acute stage* occurs with the initial burst of viremia and is characterized by high fever, thrombocytopenia, and nonspecific signs of malaise, including lethargy and inappetence. Ecchymoses and petechiae may also be detected on the mucous membranes. During the *chronic stage,* similar clinical features occur during recurrent episodes of viremia, interspersed with periods of clinical quiescence and low viremia. Throughout the chronic stage the clinical episodes tend to diminish gradually in severity and duration. The *inapparent stage* occurs once levels of viremia are immunologically contained and no clinical signs are detected. Horses experiencing clinical disease at any point may develop DIC and die. In addition, episodes of stress, including transportation, racing, and extreme temperatures, may precipitate clinical disease. Furthermore, corticosteroids have been used experimentally to induce recrudescence of clinical disease.[163]

Other chronic manifestations of EIA include the development of dependent edema, weight loss, anemia, and other ill-thrift signs. Rare manifestations that may develop include leukoencephalitis and enterocolitis.[164] The expression of clinical disease, particularly during acute infection, likely involves multiple factors, including inoculating dose, virulence factors of the inoculating viral strain, immune status and immunogenetics of the host, age, and stress. Indeed, clinical disease occurs concomitantly with high-titer viremia. Horses with high-titer viremia pose the greatest risk of transmission to uninfected horses.

Lentiviruses have a DNA-dependent RNA polymerase (reverse transcriptase) that misincorporates nucleotides, resulting in changes in the viral genome.[165] This mechanism allows for generation of viral variants that differ genetically from preexisting ones. As a result, genetic and antigenic variation of epitopes for neutralizing antibody and cytotoxic T lymphocytes allows viral escape from adaptive immune responses.[166,167] Antigenic variation plays a central role in recurrence of clinical disease throughout the chronic stage of infection and thwarts attempts to develop an effective vaccine.[165]

The EIA virus can replicate effectively in monocytes, dendritic cells, and tissue macrophages.[168–170] In addition, EIAV has been shown to replicate in endothelial cells.[171] EIAV replication in endothelial cells may play a role in the development of DIC by viral damage to endothelial cells, with subsequent exposure of subendothelium.[171] This in turn could lead to platelet aggregation and formation of thrombi.[172] In addition, damaged endothelium may result in development of dependent tissue edema by transudation of fluid through compromised small vessels.[171]

37.14.3 Necropsy Findings and Clinical Pathology

Necropsy examination of horses that die of EIA may demonstrate splenomegaly, lymphadenopathy, hepatomegaly, pronounced hepatic lobular architecture, ecchymoses of the mucosa and viscera, dependent subcutaneous edema, and thrombotic disease of small vessels. Histologic findings may include a mononuclear cell infiltrate of periportal regions of the liver, adrenals, spleen, lymph nodes, meninges, and lungs. Hemosiderophages are frequently detected in the spleen, lymph nodes, liver, and bone marrow. Glomerulonephritis from immune complex deposition is often observed.

Clinicopathologic abnormalities vary depending on the stage and severity of infection. During clinical disease, a frequently profound thrombocytopenia develops concurrently with each successive episode of fever. Platelet function of EIAV-infected horses has been demonstrated to be hypofunctional, possibly exacerbating bleeding tendencies and the progression to DIC in clinically affected equids.[173] Anemia from intravascular hemolysis, extravascular hemolysis, and depression of bone marrow erythropoiesis may progressively develop during the chronic stage of infection.[174] During the inapparent stage, horses typically have increased plasma total solids and globulin concentrations, mild anemia, and decreased albumin concentration.[175] Polyclonal B-cell activation is also evident, suggesting chronic antigenic stimulation despite clinical quiescence.[175] Concomitant fever and thrombocytopenia should prompt immediate consideration of EIA. A history of recurring fever is also suggestive of EIA, particularly when other causes of fever have been ruled out.

37.14.4 Prevention, Control, and Regulatory Considerations

It is well recognized that EIAV seroprevalence varies with the region of the United States.[174] States considered at a high risk include Texas, Oklahoma, Louisiana, and Arkansas, whereas the mid-Atlantic area, New England, Alaska, and Hawaii are considered low-risk regions. The remaining states are classified as intermediate-risk areas. Despite regional differences in risk to noninfected horses, sporadic outbreaks do occur. Veterinarians should therefore encourage all horse owners to test for EIAV annually, test new arrivals, and maintain good fly control. In addition, the veterinary community should encourage organizers of equestrian events to require proof of seronegativity of attending horses. 1162 1163

Once a seroreactor is identified, all contact horses are quarantined and undergo testing until two negative test results at 30- to 60-day intervals are obtained for all individuals in the quarantined herd.[162] The required interval is based on the need to allow recently infected horses to seroconvert. Seroreactors may be either quarantined or euthanized, depending on state regulations. Quarantined horses must be at least 200 yards (180 m) from seronegative animals, the distance shown to be sufficient to obviate viral spread by insect vectors. In addition, seroreactors remaining in permanent quarantine need to be identified. A USDA code number followed by the letter A is assigned to the quarantined horse and permanently applied to the horse as a brand or lip tattoo.

Because an eradication program has never been implemented in the United States for EIA, persistence of reservoirs of horses infected with EIAV must be expected. Indeed, the vast majority of horses in the United States are not tested on an annual basis. To encourage horse owners voluntarily to maintain vigorous surveillance testing, the veterinary community needs to educate owners about the consequences of infection by EIAV. Horse owners are often unprepared to deal with the financial and emotional losses associated with detection of a horse seropositive for EIAV.

37.15 IMMUNE-MEDIATED HEMOLYTIC ANEMIA

37.15.1 Autoimmune Hemolytic Anemia

GARY P. CARLSON

37.15.1.1 Definition and Etiology

Autoimmune hemolytic anemia is associated with the production of autologous antibodies directed against the patient's own RBCs. These antibodies combine with complement and antigens on the RBC membrane, leading to the rapid removal of affected RBCs from the circulation and their accelerated destruction. Autoimmune hemolytic anemia occurs rarely as a primary idiopathic disorder[176,177]; more often it is found secondarily associated with some other primary disease process.[176] An idiopathic immune-mediated hemolytic anemia has been reported in a calf[177] and pony.[178]

37.15.1.2 Clinical Signs and Differential Diagnosis

The presenting clinical signs of animals with autoimmune hemolytic anemia are quite variable, depending on the degree of anemia and the primary disease. Animals with marked anemia (PCV <15%) manifest signs typical of those seen in any animal with a severe hemolytic anemia (i.e., depression, pale mucous

membranes, variable icterus, elevated heart and respiratory rate, variable to intermittent fever). Secondary autoimmune hemolytic anemia in horses has been associated most often with some other primary problem, such as purpura hemorrhagica, lymphoma, other neoplasms, protein-losing enteropathy, or chronic bacterial infections.[179,180] Clinical features are typical of the primary problem, with additional findings of a hemolytic anemia. In humans, exposure to a wide variety of drugs has been causally associated with the development of autoimmune hemolytic anemia. A number of studies report an association between procaine penicillin and autoimmune hemolytic anemia in horses.[82,181–185] Autoimmune hemolytic anemia was reported in a 10-year-old horse treated with trimethoprim-sulfamethoxazole.[186] This apparently occurs rarely, perhaps only in specific individuals, but drug history should be ascertained in all animals with an otherwise unexplained hemolytic anemia.

The anemia in cattle with anaplasmosis and babesiosis or in horses with equine infectious anemia, piroplasmosis, or ehrlichiosis is largely the result of an immune-mediated hemolytic process. These diseases are discussed fully elsewhere in this book.

37.15.1.3

Clinical Pathology

The hemolytic process often is rapid and persistent, leading to a pronounced anemia. The hematologic features are those typically expected for a responsive hemolytic anemia. The anemia often is progressive and may become severe, even life threatening (i.e., PCV <10%). Erythrophagocytosis and autoagglutination may be noted on blood smears. Spherocytosis may be difficult to recognize in large animals because of the relatively small cell size and lack of a clear area or central pallor of the erythrocytes from these species. If the process has been present for 4 days or more, hematologic evidence of active erythropoietic response may be seen in the peripheral blood of all species except the horse. This evidence of bone marrow response is a favorable prognostic indicator, even when the anemia is quite advanced. A moderate neutrophilic leukocytosis is a common feature, and thrombocytopenia may be noted in some individuals if the autoimmune process is directed at platelets and megakaryocytes, as well as the erythrocytes.

37.15.1.4

Diagnosis

Documentation of the presence of antierythrocyte antibodies and complement on the RBC membrane is based on the direct Coombs' test. The indirect Coombs' test detects antierythrocyte antibody in the serum. It is important to remember that the Coombs' test is based on species-specific reagents. These reagents are commercially available in the United States for small animals and horses, and not all diagnostic laboratories will have suitable Coombs' reagents for other species. Special procedures may be necessary to adsorb these reagents to avoid nonspecific reactions. Multivalent Coombs' reagent directed against IgG, IgM, and complement is most often used. The Coombs' test usually is conducted at body temperature and also in the cold. A positive reaction at body temperature indicates that the antibodies are primarily IgG. These warm antibodies are associated more frequently with anemia, generally produce a more severe anemia, and tend to be more responsive to corticosteroids than the cold-reacting antibodies. The cold-reacting antibodies detected with the saline agglutination test run at 25° C and 4° C (39° F and 77° F) are primarily of the IgM class. Exposure to a cold environment may be necessary to produce clinical signs associated with cold agglutinin disease. Both the warm-reacting and the cold-reacting antibodies are capable of fixing complement. Unfortunately, the Coombs' test is not always positive in affected animals. Approximately one third of human and canine patients with autoimmune hemolytic anemia have a negative direct Coombs' test, possibly because of low concentrations of antibody or low binding to the RBC membrane. The diagnosis in these patients depends on ruling out other causes of a responsive hemolytic anemia and on the response to

corticosteroid therapy. Direct immunofluorescence with flow cytometry was used to determine the classes of antibody bound to erythrocytes in three horses and 12 dogs with immune-mediated hemolytic anemia. The three horses had surface-bound IgG, including a horse with suspected penicillin-induced hemolytic anemia, a foal with neonatal isoerythrolysis, and a foal with clostridial septicemia.[187] 1163 1164

A substantial proportion of otherwise normal horses have small amounts of cold-reacting Coombs' antibodies, and spontaneous agglutination may be noted in blood sample tubes exposed to the cold. In most cases these cold agglutinins appear to occur naturally and, at low levels, are of little clinical significance. Prior treatment with corticosteroids may inhibit antibody production and could lead to a false-negative Coombs' test.

37.15.1.5 Pathophysiology

Autoimmune hemolytic anemia rarely has been reported as a primary or idiopathic process in large animals; however, immune-mediated anemia occurs more often as a secondary problem (1) in association with certain types of neoplasia; (2) with a variety of viral, bacterial, rickettsial, and protozoal infections; (3) after exposure to certain drugs; or (4) in association with other immune-mediated disorders, such as systemic lupus erythematosus.[188] The initiating factors for this autoimmune disorder are not completely understood but may be related to alterations in the RBC membrane through direct or indirect injury, which elicits an abnormal response by the immune system. The RBC membrane is no longer recognized as “self” and is treated as a foreign antigen. Alternately, changes in the immune system or stimulation by some other antigenic source may result in production of antibodies with a misdirected cross-reactivity with the patient's own normal erythrocytes. Structural and functional changes in the RBC membrane are induced by the antigen-antibody reaction and complement fixation. The complement-fixing IgG or IgM antigen-antibody reaction may produce sufficient RBC damage to result in intravascular lysis of erythrocytes, but more often, affected cells are removed from the circulation at a rapid rate by the reticuloendothelial system of the liver and spleen. Partial phagocytosis of affected cells may result in spherocyte formation. Although the presence of spherocytes on blood smears is a characteristic diagnostic feature in human and canine patients with autoimmune hemolytic anemia, the relatively small size of RBCs of most large domestic animals may make it difficult to recognize spherocytes.

37.15.1.6 Treatment and Prognosis

The approach to treatment of autoimmune hemolytic anemia depends on the causal factors. If the animal has a history of drug therapy, it is advisable to discontinue medication or to change to another class of drug. Patients with primary or idiopathic autoimmune hemolytic anemia may be the best candidates for treatment. Immune-mediated hemolytic anemias secondary to other diseases can only be managed if the primary problem is amenable to treatment. Thus, treatment of an immune-mediated hemolytic anemia in a patient with extensive lymphoreticular neoplasia is likely to be unrewarding, and thorough diagnostic efforts should precede case selection for treatment. Although immune-mediated processes are responsible for hemolytic anemia in a number of infectious diseases, therapy must be directed at the primary agent, and corticosteroids are contraindicated in these diseases. Corticosteroids can cause recrudescence of viremia in horses with EIA, and a negative Coggins' test should be a prerequisite to treatment of horses with an autoimmune hemolytic anemia of undetermined cause.

Treatment of autoimmune hemolytic anemia is directed at providing supportive care and interrupting the immune response responsible for antibody production. This is usually accomplished with systemic

glucocorticoids. For a 450-kg horse, dexamethasone is recommended at an initial dosage of 30 to 40 mg/day given parenterally. This rate is continued for 3 to 5 days, then decreased gradually over 7 to 14 days, depending on the response to therapy; the hematologic response should be closely monitored. If there has been no response in 5 to 7 days, the diagnosis of autoimmune hemolytic anemia should be reviewed, and potential causes of bone marrow suppression should be evaluated. Once the hemolytic process is well under control, oral prednisolone can be given at 400 to 500 mg daily. Human patients and small animals with immune-mediated hemolytic anemia unresponsive to corticosteroids are often treated with cyclophosphamide. There is one report of successful management of a horse with cyclophosphamide and azathioprine when the anemia failed to respond to corticosteroids.[189] Supportive care consists of providing a quiet, restful environment and good nutrition, including vitamin supplementation. Iron- and copper-containing hematinics are generally of little benefit because neither of these elements is lost with hemolytic anemia. Blood transfusion is also of little benefit because it is often impossible to find a compatible donor, and the transfused cells are rapidly removed from the circulation. Blood transfusion should not be administered unless the anemia is life threatening and the immune response can be controlled with corticosteroids.

37.15.2 Neonatal Isoerythrolysis in Horse and Mule Foals

MONICA ALEMAN

Neonatal isoerythrolysis (NI) is the most common alloimmune disease in neonatal foals 7.5 hours to 12 days old (median. 2.5 days).[190] NI is characterized by hemolytic anemia, icterus, and hemoglobinuria. Clinicopathologic abnormalities include anemia, high serum indirect and direct bilirubin concentrations, and sorbitol dehydrogenase activity. NI is caused by a blood group incompatibility between the foal and dam. The foal inherits from the sire and expresses an erythrocyte antigen (alloantigen) that is not present in the mare. The hemolytic syndrome is mediated by maternal antibodies against foal erythrocytes (alloantibodies) absorbed from colostrum. Blood factors associated with NI in horse foals are Qa, Qb, Qc, Aa, Pa, and Dg, and donkey factor in mule foals.[190] The most common antigens are Qa and Aa. Foals with NI may also present with alloimmune thrombocytopenia. (See Chapters 19 and 53.)

37.16 HEINZ BODY HEMOLYTIC ANEMIA

GARY P. CARLSON

MONICA ALEMAN

37.16.1 Definition and Etiology

An acute hemolytic anemia can develop after exposure to a variety of oxidizing agents. These include drugs such as phenothiazine, methylene blue, and acetylphenylhydrazine and plants such as wild or domestic onions, members of the Brassica family (rape or kale), and wilted or dried leaves of the red maple *(Acer rubrum)*.[191–197] Red maple toxicosis (RMT) has been reported in horses, zebras, and alpacas.[195,198–200] Heinz body hemolytic anemia also occurs in sheep on specially formulated diets that are low in molybdenum, which results in chronic copper toxicity, as herd problems in cattle grazing rye grass *(Secale cereale)*[201] or selenium-deficient pastures in Florida,[202] and with selenium deficiency as a contributing factor in postparturient hemoglobinuria of cattle in New Zealand.[203] These agents produce or allow oxidative denaturation of hemoglobin and resultant

aggregation of the protein globin, which appears as Heinz body inclusions within the RBCs. Heinz body anemia has been seen in association with lymphoma in a horse, possibly from failure of the reticuloendothelial system (RES) to remove the Heinz bodies, as reported in horses with EIA.[204]

37.16.2 Clinical Signs and Differential Diagnosis

Clinical signs vary with the species involved, specific toxin or toxic metabolites, amount of toxin ingested, time course of the disease process, and occurrence of complicating secondary factors, such as hemoglobin nephrosis and acute renal failure. Weakness, lethargy, anorexia, and exercise intolerance are the usual presenting complaints, and death losses can occur. Mucous membranes are generally pale with variable to marked icterus. The heart and respiratory rates are generally elevated, but rectal temperature is usually within normal limits. Horses with RMT may be subclinical or may present with lethargy, muddy or cyanotic mucous membranes, tachycardia, inappetence, weakness, colic, icterus, brown discoloration of the blood, and pigmenturia. Rarely, sudden death occurs.[200] Pyrexia and hypothermia have also been documented. Most horses develop clinical RMT during summer and fall. The high mortality rate in horses with RMT may relate to the combination of a rapidly progressive hemolytic anemia and the formation of methemoglobin. Urine output may be reduced, and the urine may be dark because of the presence of hemoglobin, methemoglobin, or bilirubin.

It is not possible to differentiate Heinz body hemolytic anemia from other potential causes of hemolytic anemia without laboratory evaluation. The absence of fever may help to differentiate these anemias from infectious causes of hemolytic anemia. History of exposure to potential oxidizing agents and the fact that these toxic plants may produce death losses or clinical signs in multiple animals at the same time should help to differentiate these cases from autoimmune hemolytic anemia.

37.16.3 Clinical Pathology

Poisoning or intoxication resulting in Heinz body formation usually causes acute and profound anemia. In the early stages a very high percentage of erythrocytes may have Heinz body inclusions. Later, as these cells are removed from the circulation and replaced by young cells from the bone marrow, the relative number of affected cells may decrease greatly. Heinz bodies are round, oval to serrated, refractile granules usually located near the cell margin or protruding from the cell and best visualized with vital stains such as crystal violet or new methylene blue applied to unfixed blood smears. Heinz bodies appear as bluish green inclusions with the new methylene blue stain. Fixing of blood smears with methanol in preparation for staining with the classic Wright's stain interferes with stain uptake, and Heinz bodies appear as a pale area within or projecting from the cell margin and can easily be missed. After the first 3 or 4 days, the anemia is usually associated with hematologic evidence of an active erythrogenic response in all species except the horse. The total plasma proteins usually remain within normal limits, and the Coombs' test is negative. Red maple poisoning also results in depleted RBCs, reduced glutathione, methemoglobinemia, increased osmotic fragility, and modest elevations of liver-derived serum enzyme activities.

The rapid and profound erythrocyte destruction may lead to hemoglobinemia and hemoglobinuria. The development of renal failure secondary to hemoglobin nephrosis is a definite risk in these animals and is reflected by modest to marked increases in the blood urea nitrogen (BUN) and creatinine, as well as changes in the urinalysis.[196,197] These parameters should be monitored in severely affected animals. As with other causes of hemolytic anemia, serum bilirubin, particularly the indirect reacting bilirubin, is elevated.

The clinicopathologic abnormalities of horses with RMT include anemia (PCV as low as 7.5%), eccentrocytes, Heinz bodies, and elevated plasma methemoglobin concentration.[200] Other significant findings consist of inflammatory leukogram and renal insufficiency (75% and 40% of cases, respectively).[200] Mild elevation of serum total bilirubin is observed in most cases, and hemoglobinuria is seen in all affected patients.

37.16.4 Pathophysiology

Heinz bodies are formed by the precipitation of oxidatively denatured hemoglobin. The hemoglobin contained within the RBC is constantly undergoing mild oxidative stress associated with oxygen transport, as well as generation of superoxide radicals and hydrogen peroxide within the cell. A number of reducing mechanisms within the RBC counteract these oxidative processes through production of NADPH and reduced glutathione. The occurrence of Heinz body hemolytic anemia could be viewed as a consequence of exposure to oxidative stresses that simply overwhelmed the cells' reductive capacity. Selenium deficiency results in a decrease in glutathione peroxidase, a selenium-containing enzyme; in special circumstances, selenium deficiency may contribute to Heinz body formation by impeding the ability of the cells to respond to oxidative stress. Substantial species variation in the rate of Heinz body formation relates to the chemical structure of hemoglobin and the efficacy of erythrocyte-reducing mechanisms in the face of oxidative stress.[191] RBCs with Heinz bodies are less deformable than normal cells and are rapidly removed from the circulation by the RES in the spleen, where they are phagocytized and broken down. Old or senescent erythrocytes are thought to be more prone to develop Heinz bodies. Splenectomy or corticosteroid therapy may alter Heinz body clearance mechanisms, allowing significant numbers of affected RBCs to remain in the circulation of otherwise normal animals.

Gallic acid is a strong oxidant present in red maple leaves. Gallic acid has been implicated in the oxidation of hemoglobin, methemoglobin formation, and Heinz body anemia.[195,196,205] Methemoglobin is the result of oxidative change of hemoglobin iron to the nonfunctional ferric state (see discussion of nitrate poisoning, Chapter 54). This is normally prevented by glutathione reductase, ascorbic acid, and reduced glutathione. Methemoglobin cannot load or transport oxygen and, when present in sufficient quantities, results in a brown color of peripheral blood and mucous membranes. An estimation of methemoglobin concentration in a blood sample can be made by comparing the hemoglobin concentration measured by the cyanmethemoglobin method, which measures all forms of hemoglobin, with that measured by the oxyhemoglobin method, which only measures oxyhemoglobin, not other forms such as methemoglobin. Methemoglobinemia and hemolytic anemia have been reported in a mare and her dam in association with decreased levels of RBC glutathione and glutathione reductase, presumably as a result of an inherited enzymatic defect.[206]

37.16.5 Treatment

Treatment primarily involves removal from the source of toxicity and provision of supportive care. Blood transfusion can be very beneficial in severely anemic patients, particularly when there is insufficient evidence of active erythropoietic response. Iron-containing hematinics are of little benefit. Intravenous fluid therapy is indicated in animals with hemoglobinuria or azotemia to reduce the potential for further renal damage. High doses of vitamin C (ascorbic acid, 50 to 100 g IV daily), together with fluids and transfusion, were thought to aid recovery in two horses with red maple poisoning.[207] One report suggests that vitamin C therapy may have little impact on survival of affected horses, and when methylene blue was used to treat the associated methemoglobinemia in two horses, both died.[208] The goal of therapy should be to improve tissue oxygenation

and perfusion and control inflammation and pain (use of NSAIDs). Horses treated with corticosteroids have an increased likelihood of death.[200]

37.16.6 Prognosis

Prognosis in animals with modest anemia and evidence of response is good if the inciting factor can be controlled or eliminated. The mortality rate of horses with experimental or naturally occurring RMT is reported to be 60% to 65%.[208] In animals with rapidly progressive and profound anemia, prognosis is poor unless blood transfusion is undertaken. Complications are associated with hypoxia, hypoperfusion, and inflammation. Horses may develop acute renal failure, colic, pyrexia, and laminitis. A recent retrospective study of 32 horses reported a fatality rate of 59%.[200] It has been proposed that the severity of anemia is associated with mortality, but the previous study showed no such association.[200]

37.17 OTHER CAUSES OF HEMOLYTIC ANEMIA

37.17.1 Intravascular Hemolysis Following Cutaneous Burns

MONICA ALEMAN

Intravascular hemolysis has been reported in horses after severe cutaneous burns affecting more than 25% of their body surface. Plasma on admission showed hemolysis along with abnormal RBC morphology, increased osmotic fragility, hemoglobinuria, azotemia, and hemoglobin pigment nephropathy.[209] The pathophysiology of hemolysis is unclear but suspected to be associated with the production of hydroxyl radicals by complement-activated neutrophils. Abnormal findings reported in humans include intravascular hemolysis, increased RBC osmotic fragility, decreased membrane deformability, RBC crenation, eccentrocytosis, spherocytosis, bud formation, fragmentation, and vesiculation.[210] Presence of these abnormalities depends on the severity of burn trauma.[210] Pseudothrombocytosis has been reported, presumably caused by the incorrect recognition by automatic counters of RBC microvesicles as platelets.[210] Early fluid therapy and free-radical scavengers have been beneficial for the treatment of burns in humans, along with supportive and wound care, control of pain and inflammation, and prophylaxis of sepsis. A recent murine study suggested that the level of plasma free hemoglobin is related to the size and depth of burn injury, which may be difficult to determine in some cases.[211]

37.17.2 L-Tryptophan—Indole Intoxication

GARY P. CARLSON

Experimental studies in ponies have demonstrated an acute hemolytic process associated with orally administered L-tryptophan, which is converted to indole in the GI tract.[212] Intoxication was associated with an acute onset of restlessness, tachypnea, intravascular hemolysis, and hemoglobinuria. At necropsy there was evidence of hemoglobinuric nephrosis and bronchiolar degeneration in some ponies. Similar clinical signs were noted after oral administration of tryptophan at 0.35 to 0.60 g/kg and indole at 0.1 to 0.2 g/kg.[212,213] Intravascular hemolysis was associated with increased osmotic fragility and with Heinz body formation in a few of the experimental ponies.

37.17.3 Water Intoxication

GARY P. CARLSON

Massive water intake may produce marked hypotonicity of the body fluids, with subsequent intravascular hemolysis of erythrocytes.[214] This problem has been described as a naturally occurring entity in milk-reared calves when first given access to unlimited quantities of water.[215,216] Severe neurologic signs may be seen, including depression, convulsions, and coma; respiratory distress, hemoglobinuria, and death losses occur in some cases. Clinicopathologic features include hemolytic anemia, hypoproteinemia, hyponatremia, hypochloremia, hyposmolality, hemoglobinuria, and hyposthenuria. A sudden decrease in serum osmolality is believed to result in osmotic lysis of erythrocytes.[217] Fragility of the erythrocytes to osmotic shock is greatest in calves between 4 and 5 months of age. Treatment is primarily a matter of temporarily restricting water and providing supportive care. Calves with marked hyponatremia (sodium 110 mmol/L) that are manifesting neurologic signs may benefit from hypertonic saline, mannitol, and corticosteroids. The goal of treatment is the restoration of serum sodium to 120 to 125 mmol/L without overcorrection. Death losses can occur in as soon as 2 hours, but most calves recover without long-term adverse effects.

37.17.4 Postparturient Hemoglobinuria

GARY P. CARLSON

A syndrome of intravascular hemolysis, hemoglobinuria, and anemia has been recognized in postparturient dairy cattle worldwide.[218] The disease occurs sporadically, and the incidence is relatively low. Affected animals are most often high-producing multiparous cows that develop clinical signs during the first month after calving.[219] Depression, decreased feed consumption, and decreased milk production are associated with hemoglobinuria, anemia, and icterus. The anemia is often marked and after 4 or 5 days is associated with evidence of a strong erythropoietic response. The precise mechanism causing the intravascular hemolysis has not been fully defined. The condition has been related to the marked hypophosphatemia often found in affected cows and the moderately low phosphate levels in unaffected herdmates. Hypophosphatemia arises from inadequate dietary phosphorus intake in animals grazing phosphorus-deficient soils or fed fodder grown on such soils. Low intracellular phosphate concentration may interfere with energy metabolism, thus affecting cell viability and the ability of RBCs to deal with potential hemolysins, such as saponins from sugar beets or alfalfa. A postparturient hemolytic problem has been described as a herd problem in New Zealand associated with copper deficiency and Heinz body formation[203] (see previous section).

Blood transfusion and supportive IV fluids are indicated in valuable cows with severe life-threatening anemia. Treatment of hypophosphatemia consists of provision of phosphate, initially as sodium acid phosphate ($NaH_2PO_4H_2O$), 60 g/300 mL of water IV, followed by oral phosphorus supplementation. Correction of dietary imbalances is indicated.

37.17.5 Copper Toxicosis

LISLE W. GEORGE

Copper is an essential nutrient for domestic animals, but excessive supplementation can result in toxicity. Copper poisoning is a common intoxication in ruminants. The toxicodynamics and clinical syndromes have been reviewed.[220–222] Lambs are most susceptible to the effects of copper, but poisonings have occurred in adult sheep, goats, and cattle. Merino sheep are more resistant than British breeds to the toxic effects of copper.[223] Cattle have been poisoned by ingesting diets containing 37 mg of copper/kg of feed for 2 years.[224] Cattle fed 12 mg or more of copper/kg have been reported to develop subclinical hepatic disease.[225]

1166
1167

37.17.6 Pathogenesis

Elemental copper is an essential trace mineral that has a narrow therapeutic window. Dietary requirements for growing sheep range between 4 and 6 parts per million (ppm), but toxicity can occur whenever sheep are exposed to diets containing as little as 10 to 20 ppm.[226–228] Phytogenous copper poisoning results from concomitant ingestion of copper at 20 ppm of food, molybdenum, and sulfate. Ingested salts of copper are absorbed through enterocytes by carrier proteins and transported to blood in loose complexes with albumin and amino acids.[229] Ionized copper is approximately 20% of the total plasma copper. Between 70% and 90% of the ionic copper is internalized by hepatocytes, where it is redistributed to bile, packaged in lysosomes in protein complexes, or used for the formation of ceruloplasmin.[229] Accumulation of copper occurs because daily hepatic biliary copper excretion amounts to less than 1% of ingested copper in ruminants.[230] Hepatic storage can buffer high levels of copper intake until the sites become saturated. At that time, hepatocytes die spontaneously or in response to environmental stress or dietary changes. Hepatocyte death causes the release of large amounts of cuprous copper into the blood. Animals that have preexisting hepatitis from pyrrolizidine alkaloids store less copper and are more susceptible to the hemolytic crisis.[223,231]

Free inorganic copper is an oxidant and can participate in Fenton's reaction. Cellular damage is related to the production of oxidative hydroxides and peroxides, but not to copper oxidation. These reactive intermediates are thought to initiate lipid peroxidation and oxidative denaturation of proteins within erythrocytes. Oxidation of heme protein produces Heinz bodies, and oxidation of the hemin produces methemoglobinemia. Oxidized erythrocytes spontaneously lyse intravascularly, or they are sequestered in the spleen and degraded to constituent amino acids. Vitamin E is also denatured. This latter reaction removes a potent antioxidative protective factor and enhances the cellular susceptibility to additional oxidants. Differences in genetic susceptibility to copper poisoning are unknown.

The hemolytic phase of copper poisoning is often initiated by noxious stimuli that could include shipping, hierarchic change, administration of oxidative drugs, starvation, or change of housing.[232] Feeding of high-protein diets has increased the resistance in sheep to the hemolytic crisis; however, the role of extra molybdenum intake in these supplemented animals was unclear.[228,233] The mechanistic relationship between the stressful events and the hepatocyte release of copper is unknown.

37.17.7 Etiology

Sources of copper that have been responsible for copper accumulation in animals include trace-mineralized salt, inappropriately formulated cereal grain mixtures, forages from pastures fertilized by swine or chicken manure,[234] orchard pastures contaminated by copper-containing fungicides, rations containing more than 20% chicken litter, and diets that contain high concentrations of palm kernel oil. Other potential sources of copper accumulation include fencing and copper piping and overdoses of parenterally administered copper salts. In one

recent case at the University of California, Davis, dairy goats were poisoned by supplementation of trace minerals that were formulated for dairy cattle.

The toxic dose of copper for each species is variable and depends on the duration of exposure, the animal's genetics, and the amount of molybdenum being fed. Diets that contain copper/molybdenum ratios greater than 6:1 are more likely to result in copper poisoning than diets with lower ratios. The interaction between the two minerals may occur in the solid phase of rumen ingesta, when insoluble and nonabsorbable complexes of copper, sulfur, molybdenum, and large—molecular-mass protein are formed. The highly complexed copper is unabsorbed and thus not toxic. High dietary intake of zinc and iron also inhibits absorption of copper, and although the precise mechanism of antagonism is unknown, the elements share a competitive affinity for metallothioneine.[235–237] Competition for this protein could alter the storage capacity for copper. Soil sulfates reduce molybdenum absorption by plants, thereby increasing the potential for pathologic accumulation of copper in herbivores.

The respective single toxic doses of copper for sheep and cattle range from 20 to 110 mg/kg and 220 to 880 mg/kg body weight. Most poisonings occur after a long-term, low-dose ingestion of the element. Copper poisoning can occur in sheep after 2 months of daily dosing of 3.5 mg/kg copper, feeding a ration that contains 20 ppm copper for several months, or after a single subcutaneous injection of copper—ethylenediaminetetraacetic acid (EDTA) salt at 2.0 mg/kg.[238] Sheep have been poisoned by subcutaneous injection of 3 to 4 mg/kg copper-calcium EDTA, but remained normal after 6 mg/kg copper methionate.[239] Sheep have died after single injections of 2 mg/kg diethylamine copper oxyquinoline sulfonate.[239] One study that fed 3.7 mg copper/kg daily for 84 days reported peak hepatic copper levels between 258 and 375 mg/kg wet weight by 26 days after the final copper feed.[240] A single dose of 50 mg copper caused acute hemolytic crisis in sheep when treated during midpregnancy. The highest incidence of hemolytic anemia occurred in Welsh sheep, with a lower cumulative incidence in Cheviot sheep.[241] Single doses of copper-calcium ETDA at 25 mg/animal has killed lambs.[242] Cumulative doses of copper ranging between 12.8 and 22 g have produced hemolytic anemia in Suffolk lambs by 42 days.

Goats may show signs of copper poisoning by 144 days after daily feeding of a ration that contains 80 mg copper/kg. Placental transfer of copper occurs, but concentrations in the tissues of lambs are not toxic, even during the hemolytic phase in the dam.

Adult cattle may be poisoned by feeding 5 g copper sulfate daily for as long as 4 months. Calves may be poisoned after 6 to 8 weeks of feeding milk replacer containing 115 ppm copper.[229,243] Horses are resistant to high dietary concentrations of copper and may remain clinically normal after prolonged feeding of diets containing levels as high as 791 ppm. In these horses, hepatic concentrations of copper at the end of the feeding period reached 4000 ppm. Adult ponies treated once with oral copper at 40 mg/kg did not develop hemolytic anemia.

37.17.8 Clinical Signs

Animals that have been exposed to high levels of copper are asymptomatic for weeks until the onset of hepatic necrosis.[244,245] Signs develop rapidly after the onset of hepatic necrosis and reflect coexisting anemia, myopathy, and neurologic, renal, or hepatic disease. Clinical signs include inappetence, lethargy, weakness, recumbency, cool extremities, pallor, and grayish discoloration of the mucous membranes. Affected animals have a greatly increased pulse rate, tachypnea, hypotension, and hypothermia. The pulse amplitude of the

linguofacial artery is decreased. Urine is dark red due to the presence of free hemoglobin products. The animals may have marked petechiation of the conjunctival mucosa. Pregnant animals often abort because of hypoxemia. Feces are dark or have yellowish discoloration, but are normally formed, and do not contain hemoglobin unless secondary abomasal ulceration has occurred. Recumbent patients usually expire without struggling. Exposed ewes that survive copper poisoning tend to have dystocia and dilation failure in subsequent lambing periods.

37.17.9 Pathology

The tissues of hemolyzing animals are pale and icteric. The serous surfaces are covered by petechial and ecchymotic hemorrhages. The liver is often pale and yellow, and the lungs are firm. The kidneys are black and have a metallic sheen because of entrapped hemoglobin. The urinary bladder of copper-poisoned animals is filled with serosanguineous urine. Microscopic changes include hemoglobinuric and tubular nephrosis, as well as necrosis of the splenic follicles and hepatocytes. There is also biliary ductular proliferation and pericholangitis.[240,246] Hepatic necrosis may be detectable by microscopic examination for as long as 412 days after poisoning. Microscopic changes in the brain of poisoned animals include spongy degeneration of the pons and brainstem.

37.17.10 Diagnosis

Normal hepatic copper concentrations in sheep have been reported as 173 ± 130 ppm (mean ± SD) and 129 ± 59 ppm (wet matter) for adults and lambs, respectively.[247] Wet matter hepatic concentrations of copper in poisoned animals were 429 ± 249 ppm. Dry weight concentrations may be greater than 3000 ppm. Hepatic concentrations are usually high before and after the hemolytic episode, but normal hepatic copper concentrations in hemolyzing animals have been reported.[238] The correlation between plasma and hepatic copper concentrations in prehemolytic animals is poor.[248,249] Copper poisoning in animals with normal plasma concentrations and near-toxic liver levels has been reported.[250] Normal plasma copper concentrations range from 13 to 20 μmol/L (0.8 to 1.2 μg/mL).[240] Serum copper concentrations range between 0.60 and 1.50 μg/mL (0.6 to 1.5 ppm). Plasma copper concentrations that range between 2.4 and 20.0 μg/mL (2.4 to 20 ppm) are diagnostic of acute toxicosis.

37.17.11 Clinical Pathology

There are no consistent hematologic changes until 24 hours before the hemolytic crisis, when sudden concentrations of cytosolic hepatic enzymes increase coincidentally with a sharp rise in plasma copper concentration. Plasma copper concentrations fall rapidly after the hemolytic crisis and are often near normal by 4 days posthemolysis.[244] The concentrations of copper within erythrocytes remain high.

Hepatic concentrations of 16 mmol copper/kg of dry matter are the threshold for development of hemolytic anemia. The half-life of copper in the liver of nontreated poisoned sheep has been estimated at 175 ± 91 days, [240] and high copper concentrations in hepatic tissues can be found for as long as 100 days after the initiation of the hemolytic episode.[248]

Kidney concentrations of copper in animals with hemolytic crisis are 15 and 50 ppm for dry and wet weight volumes, respectively. Sheep may have increased plasma concentrations of γ-glutamyltransferase (GGT) and aspartate aminotransferase (AST) for 3 days before onset of hemolysis, and glutamate dehydrogenase may be

increased for as long as 700 days after cessation of copper ingestion.[240,251] Fecal copper concentrations may exceed 10,000 ppm during the hemolytic episode.

Clinicopathologic changes that occur during the acute hemolytic crisis include Heinz body formation; intravascular hemolysis; methemoglobinemia (as much as 5%); decreased PCV; increased concentrations of plasma bilirubin, AST, GGT, alkaline phosphatase, total bilirubin, creatine kinase, creatinine, and plasma urea nitrogen; and increased plasma ceruloplasmin. Urine is dark brown to black and contains high concentrations of protein, blood, and hemoglobin casts. Microscopic examination of urine may detect erythrocytic casts and inflammatory cells.[252] Sheep that survive the hemolytic episode develop reticulocytosis by 4 days after onset of clinical signs.[253]

37.17.12 Treatment

Animals with acute hemolytic syndrome should be treated with insufflated oxygen and vitamin E (three to five daily doses of 3000 IU/dose). If PCV is less than 8%, animals should be given packed, washed homologous erythrocytes. Additional therapy should include D-penicillamine (Cuprimine* at 52 mg/kg daily for 6 days), anhydrous sodium sulphate (1 g/sheep daily for 6 days), and ammonium molybdate (100 mg/sheep daily for 6 days). D-Penicillamine therapy increases urinary copper excretion by 10- to 20-fold.[254] Single-dose therapy with D-penicillamine (28 mg/kg) increases copper excretion, but the effect is transient and insignificant for reducing the total hepatic copper load.[255]

Dietary supplementation with 7.7 ppm ammonium molybdate also results in hepatic copper concentrations that are 40% lower than in unsupplemented controls. Addition of 7 or 15 mg molybdenum for 80 days to experimentally poisoned sheep has reduced hepatic copper concentration in sheep by 34% and 46%, respectively.[256] Copper-poisoned cattle have been successfully treated with oral sodium molybdate (3 g daily) and sodium thiosulphate (5 g daily). When introduced into the sulfur-rich rumen contents, molybdenum salts complex with high—molecular-weight proteins in the solid phase of the digesta.[257] The protein-bound thiomolybdate aggregates strongly chelate copper in insoluble and indigestible complexes. Molybdenum salts also enhance biliary copper excretion and remove copper selectively from hepatic metallothioneine.[235,258,259] For poisoned cattle, top dressing of food with 500 to 1000 mg ammonium molybdate daily for 18 days greatly reduced the amount of hepatic copper.[260]

Parenterally administered ammonium tetrathiomolybdate has been recommended for treatment of acute hemolytic crises caused by copper poisoning. Intravenous administration of ammonium tetrathiomolybdate reduces both lysosomal and cytosolic copper in hepatocytes. The drug has been given at 0.2 mg/kg molybdenum (thiomolybdate), as IV injections of 50 to 100 mg twice weekly for up to 11 weeks, or as three doses of 3.4 mg/kg on alternate days and beginning at the onset of hemolytic crisis.[261–265] Concomitant administration of 36 mg xylazine IV increased copper excretion in bile by as much as 2.25-fold over controls that were treated with thiomolybdate only.[266] The parenteral administration of the thiomolybdate results in transient increases of copper concentrations in blood for as long as 24 hours. Because copper is acid insoluble, the effect is to protect the copper-exposed animals from hemolytic crises and reduce the tissue damage during an hemolytic event.[267,268] Biweekly injection of 100 mg molybdenum as tetrathiomolybdate increased daily hepatic biliary copper excretion by a factor ranging between 150% and 300%.[269]

* Merck Sharp & Dohme, Rahway, NJ.

37.17.13 Prevention

Because of the sporadic nature of the poisoning and lack of signs during the accumulative phase, copper poisoning can be difficult to prevent. Clients should be counseled to purchase concentrates with label claims for the species that are being supplemented. Copper-supplemented salts should be restricted, especially in sheep. Heavily copper-contaminated pastures can be top-dressed with molybdenum phosphate at 113 g per acre. Fencing and plumbing that contain copper sulfate or metallic copper should be removed from the environment. One study controlled the hemolytic crisis and associated mortality from copper poisoning in sheep receiving 36 mg copper/kg daily for 18 months, by subcutaneous (SC) injection of sterile ammonium tetrathiomolybdate containing 3 to 4 mg molybdenum on alternate days for three injections.[264] The sheep in this study were given either IV or SC molybdenum at dosages that amounted to 1.7 and 3.4 mg/kg ammonium tetrathiomolybdate. Addition of ammonium molybdate at 7.7 ppm and sodium sulfate at 4200 ppm reduced liver copper and decreased plasma ceruloplasmin in experimentally exposed lambs.[249]

Feeding of sodium molybdate and sodium sulfate at respective daily dosages of 20 mg and 6 g to experimentally poisoned lambs reduced hepatic copper content after 90 days.[270]

Molybdenum and sulfur protect sheep by converting ingested copper to nonabsorbable thiomolybdate complexes in the rumen. The antagonistic effects are greatest at times of rapid hepatic accumulation of copper. Addition of 3 mg/kg of food (dry matter) molybdenum as tetrathiomolybdate reduced hepatic copper accumulation by as much as 33-fold.[263] Lambs that were fed diets containing 7.7 ppm ammonium molybdate after weaning until 14 weeks of age had reduced hepatic copper and decreased ceruloplasmin concentrations.[249] Cattle can tolerate indefinite periods of feeding copper at dosages less than 0.6 mg/kg daily.[250] Addition of 220 to 420 ppm zinc may be protective against copper poisoning in sheep, but this is not used in clinical situations.[257]

37.17.14 Hemolytic Syndrome in Horses with Liver Failure

GARY P. CARLSON

A fulminant, intravascular hemolytic syndrome has been reported as a near-terminal event in horses with either acute or chronic liver failure.[271] Marked hemoglobinemia and hemoglobinuria are associated with intense icterus. The sclera and conjunctiva often take on a distinctive, deep—reddish orange color. The onset of intravascular hemolysis is sudden and rapidly progressive. The prognosis is highly unfavorable because almost all horses that develop this syndrome die or must be euthanized because of clinical deterioration.[272] Intravenous fluids, corticosteroids, and supportive care do not appear to alter the clinical course or the unfavorable outcome.

The cause of this syndrome has not been determined, but apparently it is not related to a release of hepatic copper stores. The hemolysis appears to be associated with increased erythrocyte osmotic fragility. Human patients with liver cirrhosis develop a hemolytic syndrome associated with alterations in the exchangeable lipoproteins of the RBC membrane. It is not known if a similar mechanism is responsible in horses, but morphologic alterations in the RBCs of these horses resemble the “burr cells” described in human patients.[273] Bile acids and their salts are greatly increased in liver failure and could play a contributing role in the hemolytic process. At necropsy, widespread hemorrhagic lesions that resemble those described for DIC are often present.

[273] DIC and the activation of various mediators may play a role in the terminal stages of this almost invariably fatal process.

37.17.15 "Pink Tooth," Congenital Erythropoietic Porphyria, Toxic Porphyria

GARY P. CARLSON

A rare congenital disorder of hemoglobin production inherited as an autosomal recessive trait has been recognized primarily in Holstein cattle, but it has also been reported in Shorthorns and Jamaican cattle.[274,275] This disorder is commonly called "pink tooth" and is characterized by slow growth rates in calves, photosensitization and exfoliation of nonpigmented skin when exposed to sunlight, reddish brown teeth, and modest anemia. The teeth and bones exhibit a pink fluorescence under ultraviolet (UV) light, and the urine is brownish red because of uroporphyrin. The condition is present at birth, and the metabolic defect in these cattle is a hereditary deficiency of the enzyme *uroporphyrinogen III cosynthetase,* which catalyzes an essential step in the synthesis of the porphyrin structure of hemoglobin.[275] This leads to the accumulation of uroporphyrin and coproporphyrin, which deposit in the teeth, where porphyrin is concentrated in the dentine, bones, and other tissues. Several factors contribute to the variable anemia seen in these cattle. A reduced intravascular RBC lifespan is related to the high concentration of uroporphyrin and coproporphyrin within the cells. Porphyrins may induce hemolysis and also delay maturation of the RBC series in the bone marrow, although there is often evidence of active erythropoietic response in the peripheral blood.[275]

There is no treatment for this inherited disorder, but genetic counseling is advisable. Substantial efforts have been made to reduce the incidence of pink tooth in the Holstein breed. It may be possible to detect carrier animals. Affected cattle have much lower levels of uroporphyrinogen III cosynthetase than normal cattle, and carrier animals have intermediate levels of this enzyme. Despite their rather serious problems, these cattle do reasonably well if housed indoors out of direct sunlight. The principal differential consideration is chronic fluorosis, which also produces brown discoloration of the teeth. However, the teeth of cattle with chronic fluorosis do not fluoresce under UV light.

An additional form of altered porphyrin metabolism, *congenital erythropoietic porphyria,* has been described in humans and cattle.[275] In humans the mode of inheritance is autosomal dominant, whereas in cattle the disorder appears to have a recessive pattern of inheritance and may be sex linked because it is only seen in females. The disease does not produce anemia, porphyrinuria, or discoloration of the teeth. This disorder is caused by a deficiency of ferrochelase (heme synthase), which leads to high concentrations of erythrocyte and fecal protoporphyrins. Porphyria has also been reported in swine, with a dominant pattern of inheritance.[275] There is little effect on the health of the pigs and no photosensitivity, but the teeth have reddish brown discoloration. Although similarities exist with bovine congenital erythropoietic porphyria, the precise defect in swine has not been found.

Finally, animals may develop *acquired toxic porphyrias*. This can occur with heavy metal poisonings, principally lead, but has also been produced experimentally with hexachlorobenzene and other chemicals. Lead inhibits several key enzymes of heme synthesis. Inhibition of aminolevulinate dehydrase leads to an accumulation of aminolevulinic acid, and decreased aminolevulinate dehydrase activity is a sensitive indicator of lead poisoning. Lead also inhibits ferrochelase, leading to marked elevation of erythrocyte zinc protoporphyn IX, the measurement of which provides a means of monitoring lead exposure.[275]

37.18 ## DEPRESSION ANEMIA

GARY P. CARLSON

The most common form of anemia in domestic animals is associated with inadequate erythropoiesis or bone marrow depression. Depression anemia can be caused by (1) deficiencies of vitamins or minerals that are essential for erythrocyte production, (2) systemic disease processes that interfere with normal erythropoiesis, and (3) processes that damage or displace normal bone marrow elements (Box 37-2). Depression anemia is often mild to moderate in severity and generally is only slowly progressive. Depressed erythropoiesis is occasionally associated with processes that also result in blood loss and increased rate of erythrocyte destruction. When this occurs, a profound, rapidly progressive, and potentially life-threatening anemia can develop.

With the possible exception of chronic iron or copper deficiency, depression anemia tends to be normocytic and normochromic. Bone marrow evaluation is an extremely useful diagnostic tool in animals with nutritional deficiencies or when bone marrow damage or dyscrasia is suspected. A thorough clinical evaluation and vigorous application of appropriate diagnostic procedures are necessary to establish a diagnosis of depression anemia and to determine the factors responsible for the anemia.

37.19 ## IRON DEFICIENCY ANEMIA

GARY P. CARLSON

MONICA ALEMAN

Iron is present in most forages and grains. In neonates the major source of iron is colostrum (~0.79 mg/L in mare's milk).[276] Soil, dam's feces, and milk are other important sources of iron.[276] Iron deficiency most often is associated with chronic blood loss as the result of internal or external parasitism, bleeding GI lesions, or hemostatic defects.[149] Dietary iron deficiency is seldom the sole cause of anemia, even in neonates on an all-milk diet, unless they are raised on cement or in barns or hutches with no access to the soil. A modest anemia is anticipated in veal calves. The anemia seen in some young calves during the first few days to weeks of life is apparently the result of congenital iron deficiency,[277] but the causal factors have not been determined. Altered immune functions, high incidences of infection, and reduced growth performance are reported in veal calves on low-iron diets.[278] Alterations in gastrointestinal pH may alter absorption of iron by the small intestine. States of inflammation and infection cause iron sequestration, not deficiency, by the reticuloendothelial system and lactoferrin. Iron deficiency has been well documented in calves and piglets that are housed exclusively indoors or hatches with no access to soil.[279] Absolute iron deficiency anemia is not usually reported in horses.[280–283]

37.19.1 ### Box 37-2 Causes of Depression Anemia

37.19.1.1 #### NUTRITIONAL DEFICIENCY

Iron deficiency

Copper deficiency

Cobalt deficiency

Vitamin B_{12} deficiency

Folic acid deficiency

37.19.1.2 ANEMIA OF INFLAMMATORY DISEASE

Chronic infection

Chronic inflammation

Fractures and severe trauma

Neoplasia

37.19.1.3 ANEMIA SECONDARY TO ORGAN DYSFUNCTION

Chronic liver disease

Chronic renal disease

Chronic gastrointestinal disease

Parasitism (trichostrongylosis)

37.19.1.4 BONE MARROW DAMAGE/DYSPLASIA

Myeloid and megakaryocytic bone marrow hypoplasia in standardbred horses

Bracken fern poisoning

Congenital dyserythropoiesis and keratosis in polled Hereford calves

Trichloroethylene-extracted soybean meal toxicity

Myelophthisic disorders (myeloproliferative disease, lymphoma)

Aplastic anemia

The circulating erythrocytes account for approximately two thirds of the total iron reserves found in the body. The remaining iron stores are distributed in the liver, spleen, and bone marrow. With chronic blood loss anemia, iron depletion is first indicated by decreased marrow iron, which can be appreciated with special staining of the bone marrow with Prussian blue stain for iron. As blood loss continues and iron deficiency progresses, serum iron is decreased, whereas iron binding capacity actually may increase. It is only late in this whole process that iron-deficient erythropoiesis results in the typical microcytic, hypochromic erythrocytes that generally are thought to be characteristic of iron deficiency anemia (decreased PCV, hemoglobin concentration, mean corpuscular volume, and mean corpuscular hemoglobin concentration).[149,192] Other laboratory findings include echinocytosis, keratocytosis, schistocytosis, acanthocytosis, ovalocytosis, hypoferritinemia, and hypoferremia.[280–283] The observed RBC morphologic abnormalities are thought to be caused by oxidative damage. The normal serum iron and iron-binding capacity for most domestic animals is 100 and 300 μg/dL, respectively. There is one report of a neonatal foal that had iron deficiency with refractory anemia and severe abnormal RBC morphology, but no microcytosis or hypochromasia.[283]

Treatment of iron deficiency anemia depends on evaluation of the cause and the correction or resolution of the process responsible for the chronic blood loss. Iron is usually supplied as an oral supplement or as a feed additive, and a variety of commercial preparations are available. Injectable iron dextran intended for use in baby pigs should be avoided in horses and cattle because it can induce an anaphylaxis, especially if administered repeatedly.[284] Iron cacodylate was a safe parenteral iron preparation for use in horses but is no longer readily available. An injectable iron preparation intended for use in horses was reported to result in acute iron overload, massive hepatic necrosis, and severe death losses in a group of young cattle.[285] Iron overload has resulted in acute death losses in neonatal foals fed an iron-containing microbial supplement. Iron accumulation resulting in hemochromatosis with extensive liver damage has also been reported in adult horses, although the mechanism responsible for the iron accumulation has not been explained.[286]

37.20 COPPER DEFICIENCY

GARY P. CARLSON

Copper deficiency can occur as a primary problem in milk-fed animals or in pastured animals in copper-deficient areas. More often, copper deficiency occurs secondarily in association with other trace mineral imbalances (e.g., dietary molybdenum excess) and is influenced by the sulfur and zinc content of the diet. Copper is an essential cofactor for a variety of enzymatic reactions, and copper deficiency produces a constellation of clinical signs related to impairment of these reactions.[287] Clinical signs of copper deficiency are most prominent in young, growing animals and may include reduced growth rate, rough and depigmented hair, diarrhea, osteoporosis with spontaneous fractures, and anemia. In lambs, copper deficiency can produce a demyelinating syndrome known as “swayback” or “enzootic ataxia.” Copper deficiency has also been associated with hemolytic anemia in postparturient dairy cattle in New Zealand.[285]

1170

1171

Copper plays an important role in the transport of iron from the gut to the marrow and in the incorporation of iron into the heme moiety. The anemia produced by copper deficiency is generally moderate, slowly progressive, and closely resembles iron deficiency in that it is usually a microcytic, hypochromic anemia. Bone marrow evaluation often reveals intracellular accumulations of iron known as *sideroblasts*. This finding indicates that the principal

problem is a function of altered incorporation of iron into the erythrocyte hemoglobin rather than an actual deficiency of iron. Copper deficiency can be documented by measuring serum copper as ceruloplasmin, erythrocyte superoxide dismutase, or the copper content of hair, liver, or kidney. Serum iron tends to be low in animals with copper deficiency. Copper can be supplied as a dietary supplement or as an injectable copper glycinate preparation.

37.21 VITAMIN B_{12} AND FOLIC ACID DEFICIENCY

GARY P. CARLSON

Almost all the vitamins are necessary for normal erythropoiesis, but in ruminants and horses, only deficiencies of vitamin B_{12} and folate have been associated with the development of anemia.[149] These two vitamins play essential roles in DNA synthesis. When deficiencies of both vitamins coexist, as experimentally produced in pigs, a marked macrocytic anemia with hypersegmented circulating neutrophils and giant metamyelocytes and neutrophils in the bone marrow may be found. In ruminants, vitamin B_{12} deficiency has been associated with grazing cobalt-deficient pastures. A macrocytic to normocytic anemia may be noted in these animals. Folate deficiency has been reported as a cause of a mild seasonal decline in erythrocyte parameters in horses.

37.22 ANEMIA OF INFLAMMATORY DISEASE

GARY P. CARLSON

A depression anemia associated with characteristic disturbances of iron metabolism is often found in animals with conditions that result in a chronic inflammatory response.[288,289] These conditions include chronic internal or cutaneous infections, infectious diseases, or immune-mediated processes that result in chronic inflammation, severe traumatic injury or fractures, and active malignant neoplasia. The anemia tends to be mild, slowly progressive, and of itself, of little clinical consequence. Clinical signs relate to the primary disease process; and hematologic features are those of a mild, nonresponsive anemia, often with indications of a chronic inflammatory response (neutrophilic leukocytosis, as well as monocytosis with elevated fibrinogen, total protein, and globulin). Serum iron and iron-binding capacity are decreased, but marrow iron reserves and serum ferritin are increased.[149,289]

Anemia in these animals partly results from a modest decrease in the circulating RBC lifespan, but it is primarily caused by major alterations in iron metabolism and a depressed bone marrow response to the anemia. These alterations represent part of the body's response to inflammation, which includes the release of interleukin and other mediators and the production and release of various “acute phase” proteins from the liver. The body tends to sequester iron from the circulation into storage forms primarily in the liver and bone marrow, where it is retained and is relatively unavailable for erythropoiesis. This general reaction may play a protective role by denying readily available iron to potential bacterial pathogens that require iron for rapid growth and multiplication. Iron supplementation is not indicated for the treatment of the anemia of chronic inflammation, and therapeutic effort should be directed at resolution of the primary disease process.

37.23 ANEMIA SECONDARY TO ORGAN DYSFUNCTION

GARY P. CARLSON

A mild to moderate, nonresponsive anemia can develop in patients with chronic endocrine, hepatic, renal, or GI diseases. These disorders can produce bone marrow depression by (1) reducing the production or absorption processing and the distribution of elements essential for erythropoiesis, (2) allowing the elaboration or accumulation of toxic compounds, or (3) interfering with the production or action of erythropoietin.[290,291] These effects can occur independent of alterations in iron metabolism that characterize the anemia of inflammatory disease.[289] However, should inflammatory processes be responsible for the specific organ damage or dysfunction, the same pattern of anemia as described in the previous section would apply. Specific therapy for the anemia in these patients is not indicated, and resolution of the anemia depends on successful management of the primary disease process.

Internal parasitism, particularly that associated with *Trichostrongylus* species in ruminants, can result in a marked anemia. The anemia in these animals is primarily the result of bone marrow depression, in which failure to absorb iron, copper, and essential amino acids plays a major role.

37.24 MYELOID AND MEGAKARYOCYTIC BONE MARROW HYPOPLASIA

GARY P. CARLSON

Myeloid and megakaryocytic bone marrow hypoplasia was reported in eight young standardbred horses sired by the same stallion.[292] Clinical signs were variable and in individual horses included nonhealing wounds, nonresponive fevers, pleuritis, pneumonia, ataxia, hemoperitoneum, and bleeding into the bowel. Seven horses died or were euthanized. The principal laboratory findings were a variable RBC count from normal to modest to marked anemia, moderate to profound neutropenia, and an intermittent thrombocytopenia in most of the horses. There appeared to be a cyclic variation in neutrophil and platelet counts. A bone marrow microenvironment or growth factor defect is suspected as the cause of this problem because myeloid progenitor cells were present and were able to respond to exogenous growth factors. A familial basis for the disease is suspected.[292]

37.25 APLASTIC ANEMIA

DEBRA DEEM MORRIS

Aplastic anemia is a stem cell disorder characterized by reduced marrow production of all blood components in the absence of a primary disease process infiltrating the bone marrow or suppressing hematopoiesis.[293,294] 1171
Peripheral pancytopenia secondary to marrow aplasia is apparently very uncommon in horses, although idiopathic 1172
hypoplastic anemia has been reported,[295–297] as well as rare cases associated with the use of phenylbutazone.[290,298] Hemorrhagic diathesis caused by thrombocytopenia is often the first indication of disease, manifested by epistaxis, mucosal petechiae, or prolonged hemorrhage after trauma or injections. Pallor may be present, with other signs of anemia (e.g., reduced exercise tolerance) depending on the severity and rapidity by which aplasia progresses. Neutropenia causes increased susceptibility to infections, which may result in intermittent fever or weight loss. The production of lymphocytes is reportedly not impaired; however, absolute lymphopenia can occur in aplastic anemia. Circulating lymphocytes are often highly reactive, producing the suspicion of neoplasia or a preleukemic syndrome.[290]

Marrow aplasia in humans is usually termed *idiopathic,* although some cases are associated with exposure to a drug, chemical, ionizing radiation, or presence of another disease.[294] Marrow failure results from damage to the

hematopoietic stem cell compartment. This may be in the form of DNA damage to stem cells or depletion of later progenitor cells by a cycle-active agent. Some cases of marrow aplasia appear to be immune mediated, either genetically determined or incited by a particular viral infection or drug exposure.

The diagnosis of aplastic anemia is based on the combination of peripheral pancytopenia and bone marrow hypoplasia with fatty replacement. Because the normal erythrocyte lifespan in horses is approximately 140 days and in cattle exceeds 160 days,[299] neutropenia with no left shift and thrombocytopenia are earlier hematologic manifestations.

The major aims in treatment of aplastic anemia are to remove the animal from suspected causative agents and to provide supportive care, in the hope that spontaneous remission will occur. Broad-spectrum antimicrobials are necessary to control infections. Blood transfusions are rarely indicated, and platelet transfusion should be reserved for severe bleeding episodes, which rarely occur. Bone marrow transplantation is used with some success in humans, although graft-versus-host disease poses significant risk. The latter would presumably limit this therapy in horses, and too few horses with aplastic anemia have been studied to give a clear indication of prognosis.

Bracken fern toxicosis in ruminants causes bone marrow depression and subsequent pancytopenia.[48,299] Most field outbreaks of the disease occur in cattle. The toxic effects of the plant are cumulative, and clinical signs occur suddenly 2 to 8 weeks after cattle gain access to the plant. Clinical signs include fever, melena, epistaxis, hematuria, mucosal petechiae, hyphema, and bleeding from the eyes and vagina. Hematology reveals a platelet count less than 40,000/μL and profound leukopenia with essentially no neutrophils present. Death may follow in 1 to 3 days as a result of the combined effects of multiple internal hemorrhages and bacteremia. The aplastic anemia factor in bracken fern has not been identified, although ptaquiloside has been suggested.[299] Necropsy of cattle with bracken fern toxicosis reveals multiple hemorrhages throughout most tissues, necrotic GI tract ulcers, and pale bone marrow. Antibiotics and blood and platelet transfusions may be appropriate but cattle with advanced bracken fern toxicosis (platelet count <50,000/μL; leukocyte count <2000/μL) usually die.

37.26 PARADOXIC ERYTHROID HYPOPLASIA

MONICA ALEMAN

Recombinant human erythropoietin (rhEPO) has been used in racehorses to enhance their athletic activity by stimulating erythrocyte production in the bone marrow. Mild to moderate anemia and paradoxic erythroid hypoplasia based on bone marrow cytology were reported in two standardbred race horses after rhEPO administration.[300] Serum from these horses inhibited the rhEPO-induced activity of mouse bone marrow in vitro. The degree of inhibition was inversely proportional to the amount of exogenous rhEPO added to the serum, suggesting the presence of anti-rhEPO antibodies. Anti-rhEPO antibodies to exogenous rhEPO likely cross-reacted with the horses' endogenous rhEPO. These horses were treated with dexamethasone at adjustable dosages according to response and returned to their usual athletic activity.

37.27 ERYTHROCYTOSIS (POLYCYTHEMIA)

DEBRA DEEM MORRIS

Absolute erythrocytosis is caused by increased erythropoiesis that creates a circulating erythrocyte mass above normal for the species. Relative erythrocytosis caused by hemoconcentration, endotoxemia, and splenic contraction (horses) must be ruled out because these conditions are much more common in large animals than

absolute erythrocytosis. Diagnosis of absolute erythrocytosis is based on persistently elevated packed cell volume (PCV), hemoglobin, and erythrocyte count, without clinical evidence of shock or dehydration and without response to intravenous fluid therapy. Primary erythrocytosis is associated with normal arterial oxygen tension and reduced plasma erythropoietin, whereas secondary erythrocytosis is caused by increased production of erythropoietin.

All disorders characterized by an absolute erythrocytosis share clinical manifestations caused by expanded blood volume and increased blood viscosity. Generalized vascular expansion and venous engorgement cause the characteristic "muddy" hyperemia of mucous membranes. A marked decrease in cardiac output accompanies blood hyperviscosity and ultimately impairs tissue oxygenation, producing the vague signs of lethargy and weight loss. There may be an increase in thrombotic complications such as laminitis and renal failure.

37.28 CONGENITAL ERYTHROCYTOSIS

Familial erythrocytosis, described in cattle[301] and humans,[302] is caused by autonomous erythropoietin production without a demonstrable lesion. Congenital erythrocytosis is thus a form of inappropriate secondary erythrocytosis. Chronic hypoxia should be ruled out by measuring the arterial oxygen concentration. The only way to definitively differentiate secondary erythrocytosis from primary erythrocytosis is by determination of serum erythropoietin.

37.29 ACQUIRED ERYTHROCYTOSIS

37.29.1 Primary Erythrocytosis

Polycythemia vera, an idiopathic myeloproliferative disorder characterized by excessive proliferation of erythroid, myeloid, and megakaryocytic elements, has not been reported in large animals.

37.29.2 Secondary Erythrocytosis

37.29.2.1 PHYSIOLOGICALLY APPROPRIATE ERYTHROCYTOSIS

In domestic animals, absolute erythrocytosis is usually secondary to chronic diseases that produce tissue hypoxia. Chronic tissue hypoxia that attends residence at high altitude, congenital heart defects that produce right-to-left shunting, and some forms of chronic pulmonary disease induce a compensatory increase in plasma erythropoietin that results in absolute secondary erythrocytosis.[303]

1172

1173

The partial pressure of oxygen (P_{O_2}) in capillaries must be maintained close to 40 mm Hg to ensure adequate off-loading of oxygen to tissues. At elevated altitudes, diminished atmospheric oxygen tension produces a much smaller alveolar capillary P_{O_2} gradient and an inadequate driving force for tissue oxygenation. Erythropoietin production in response to hypoxia causes erythrocytosis to increase the oxygen-carrying capacity of circulating blood. Cattle are most susceptible to the effects of high altitude, and some develop polycythemia at 1800 m (5940 ft) above sea level.[48] Horses develop an increased erythrocyte mass above 2200 m (7260 ft), especially when in training. Sheep are similar to cattle, but goats are apparently least susceptible to elevation hypoxia.

Congenital cardiac disorders that produce right-to-left shunts are a common cause for absolute erythrocytosis in large animals. Tetralogy of Fallot is the most common defect to cause shunting of unoxygenated blood

into the peripheral circulation, although a number of other defects, including the most common ventricular septal defect, may eventually result in right-to-left shunting and secondary erythrocytosis.[304]

Chronic impairment of alveolar ventilation may eventually cause erythrocytosis, although most chronic pulmonic diseases in large animals are not associated with significant hypoxemia. Chronic obstructive pulmonary disease in horses may produce enough ventilation/perfusion mismatching to reduce the pressure of arterial oxygen below normal, but the resultant hypoxemia is insufficient to induce erythrocytosis.

37.29.2.2 PHYSIOLOGICALLY INAPPROPRIATE ERYTHROCYTOSIS

Inappropriate elaboration of erythropoietin (i.e., normal Po_2 and secondary erythrocytosis) may rarely accompany renal, hepatic, or endocrine disorders, especially those caused by neoplasia. Secondary erythrocytosis may accompany nonmalignant renal disorders, in which local intrarenal ischemia is believed to mediate increased erythropoietin production. Paraneoplastic erythrocytosis with normal serum erythropoietin is caused by tumor production of androgenic steroids or a protein with erythropoietin-like action.[305] Increased plasma erythropoietin and secondary erythrocytosis have been identified in horses with hepatocellular carcinoma.[303,306] Erythrocytosis was described in a horse with hepatoblastoma[307] and in another with lymphoma,[308] but serum erythropoietin levels (as measured by a human assay) were normal in both cases. In the horse with lymphoma, erythropoietin gene expression was identified in the lymphoma tissue. Typically, the diagnosis of inappropriate secondary erythrocytosis is based on elevated serum erythropoietin in the absence of hypoxemia. Elevated serum erythropoietin may not be demonstrated because of the nature of the assay or other compounds causing erythrocytosis.

37.30 TREATMENT OF ERYTHROCYTOSIS

When erythrocytosis is not in response to an appropriate physiologic stimulus (e.g., primary erythrocytosis, inappropriate secondary erythrocytosis), phlebotomy to keep the PCV less than 50% is the mainstay of the treatment to control hypervolemia and blood hyperviscosity. Initially, 2 to 4 L of blood may need to be removed every 2 to 3 days, but as iron deficiency supervenes, the frequency of phlebotomy may be reduced. The myelosuppressive drug hydroxyurea, used in humans and dogs with polycythemia vera,[302,309] has not been tried in large animals.

The management of appropriate secondary erythrocytosis is more complex because there is a need for increased oxygen-carrying capacity of the blood. The beneficial effect of expanded RBC mass is ultimately offset by the detrimental effect of increased blood viscosity on oxygen delivery. Oxygen delivery is impaired when the PCV exceeds 60%, although continued erythropoietin output may result in overcompensation. Phlebotomy is indicated when the PCV is greater than 60%, but the optimum PCV for patients residing at high altitudes or those with right-to-left cardiac shunts must be determined by trial and error.

The long-term prognosis for patients with erythrocytosis is determined by the severity and cause of the disorder. Congenital cardiac defects, neoplastic diseases, and chronic organ insufficiency carry a guarded to poor prognosis. Familial or primary erythrocytosis may be managed by phlebotomy, although there are no long-term follow-ups for large animals with these disorders.

37.31 PROLIFERATIVE DISORDERS OF LYMPHOID AND MYELOID SYSTEMS

The lymphoproliferative disorders reported in horses include lymphoma, lymphocytic leukemia, and plasma cell myeloma. The myeloproliferative disorders include myeloid leukemias and malignant histiocytosis.[310] The following sections describe lymphoma, leukemia, and myeloma.

37.32 BOVINE LYMPHOMA

JOHN ANGELOS

MARK C. THURMOND

Bovine lymphoma (lymphosarcoma) is characterized in terms of the frequency of occurrence (sporadic or endemic/enzootic), age at onset, organ involvement, and associated etiologic agent. Sporadic bovine lymphoma occurs as generalized lymphadenopathy in calves (calf or juvenile form), as thymic involvement in cattle between 6 months and 2 years of age (thymic or adolescent form), and as a cutaneous form in cattle between 1 and 3 years of age. Lymphoid tumors of cattle with sporadic bovine lymphoma are of the B-cell or T-cell lineage.[311] The most common form of lymphoma appears endemically in adult cattle more than 2 years of age and is associated with *bovine leukemia virus* (BLV) infection and typically involves multiple organ systems; BLV-associated lymphomas of adult cattle are of the B-cell lineage.[312] BLV is classified in the genus *Deltaretrovirus,* subfamily Orthoretrovirinae, and family Retroviridae.

37.32.1 Sporadic Lymphoma

37.32.1.1 CALF OR JUVENILE FORM

The prevalence rate of juvenile lymphoma is unknown, but this form of lymphoma is rare, and multiple cases may be seen in the same herd. The cause of juvenile sporadic lymphoma is unknown and does not appear to be associated with BLV infection.[313]

The age at onset ranges from 3 to 6 months, but can be seen in calves as young as 1 month or in cattle as old as 3 years. There have been reports of fetal involvement with the calf form.[314] Calves generally present with a history of slight to moderate depression, weight loss, weakness (mainly in older calves and despite good appetite), or lymphadenopathy (mainly in younger calves).[315] The onset of signs can be sudden (within a week).

Physical examination may reveal generalized bilateral enlargement of lymph nodes, particularly the deep cervical and parotid nodes and occasionally the popliteal and hemonodes. Moderate to marked enlargement may be noted for the iliac and mandibular nodes. Rarely, node enlargement is not generalized but is restricted to a regional anatomic site.[313,315] Enlarged nodes tend to be smooth and firm and are not hot or painful. Mucous membranes are usually pale as a result of anemia. Tachycardia, tachypnea, hyperpnea, cough, and harsh respiratory sounds may be evident on auscultation. Less frequently reported signs include fever, ruminal tympany, an enlarged liver, ataxia, and diarrhea.[315]

Hematologic features include a microcytic hypochromic anemia, low hemoglobin concentration (<7 g/100 mL),[316] low PCV (typically mid-20s), and a leukocytosis primarily caused by a lymphocytosis.[313,315–317] Bone marrow examinations may reveal an elevated myeloid/erythroid ratio, with massive neoplastic infiltration in some calves.[316] Affected calves also tend to have low serum globulin and elevated AST. Neoplastic involvement of a variety of organs, including the spleen, heart, kidney, liver, pancreas, uterus, and thymus, may occur.[313,315,316] Less thymic involvement occurs compared with the thymic form of lymphoma; neoplastic tissue is found only as small, microscopic nodules.[316] Subperiosteal neoplastic infiltration may produce spinal cord compression and result in paresis.[316] The disease is rapidly progressive and usually fatal within 2 to 8 weeks of onset.

37.32.1.2

THYMIC OR ADOLESCENT FORM

The thymic form of lymphoma is very rare. The disease is usually seen in cattle 6 to 24 months of age but may occur in newborn calves and cattle up to 4 years of age.[315] Clinical signs are produced by space-occupying lesions in the neck or thorax.[318] Metastatic mammary lymphoma along with thymic lymphoma was reported in a 3-year-old beef heifer.[319] Cattle with thymic lymphoma typically present with brisket enlargement or firm swelling in the presternal area of the brisket, associated with pitting edema.[320] Loss in body condition, rumen tympany, and dysphagia are common. Bloat may occur as a result of inability to eructate ruminal gas as a result of a space-occupying lesion around the esophagus.[318] Although generalized lymphadenopathy is uncommon, enlarged superficial cervical and prescapular nodes are usually observed. The jugular veins are distended and nonpulsating; there may be muffled heart sounds and diminished resonance on thoracic percussion. Tachycardia, dyspnea, coughing, or respiratory distress may be present. Hematologic features are generally unremarkable. Anemia is not a consistent feature, and lymphocytosis is only seen occasionally. The course of the disease from the time of recognition is generally from 2 to 9 weeks, but poor condition may have been present for several months before presentation.[321] The disease is fatal, often as a consequence of bloat.

Although thymic lymphoma is not associated with BLV infection, there has been one report of a BLV-positive 18-month-old heifer with thymic lymphoma. In situ PCR was used to detect the presence of BLV proviral DNA in lymphocytes of the thymus and in liver and kidney epithelium.[322]

37.32.1.3

ATYPICAL FORMS

A 7-month-old Holstein heifer with diffuse swelling over the left thigh, difficult ambulation, and peroneal and tibial nerve deficit had an infiltrative B-cell lymphoma involving the semitendinosus, semimembranosus, and gluteal muscles.[323] This heifer was serologically positive for BLV antibody, but the possibility of maternally derived antibody could not be ruled out. In another case report, the external and internal surfaces of the trachea of an 18-month-old Friesian heifer with cutaneous lymphoid tumors also had extensive lymphoid nodules covering the external and luminal surfaces of the trachea.[324] An 8- to 9-year-old beef cow with weight loss was reported with pleural and pericardial invasion with a lymphoid tumor of T-cell lineage; the animal tested negative for BLV on PCR.[325] Four of 10 cattle 3 years of age or younger diagnosed with sporadic lymphoma had BLV provirus in tumor DNA, as detected by PCR, and a possible role for BLV in some cases of sporadic lymphoma of cattle has been suggested.[326]

37.32.1.4 CUTANEOUS FORM

Cutaneous lymphoma is not as age specific as the other forms of sporadic lymphoma and may affect cattle between 1 and 3 years of age. The history may reveal an initial period of 1 to 3 months during which cutaneous swellings are observed around the anus, vulva, escutcheon, shoulders, or flank. These signs may regress and subsequently recur.[327] Lesions tend to be raised and can be ulcerated. They are generally about 2 to 3 cm in diameter with necrotic centers and may be painful on palpation. Other clinical signs depend on additional organ system involvement of the tumor and may include cardiac insufficiency, with brisket edema extending along the ventral abdomen and jugular pulsation. Pulse and respiration may be elevated as a result of anemia. Hematologic features include anemia and presence of atypical lymphocytes. The mandibular, prescapular, prefemoral, and supramammary lymph nodes are usually enlarged.[328]

At necropsy, a variety of organs may be involved, including heart, brain, skin, spinal cord, liver, lung, kidney, and abomasum. The massive lymphoid infiltration of the skin resembles the clinical manifestations of mycosis fungoides of humans.[314] In a report of a 12-month-old red Holstein heifer with cutaneous T-cell lymphoma, serum activity of lactate dehydrogenase (LDH) was moderately increased despite normal to minimally increased activities of liver and muscle specific enzymes.[329]

37.32.1.5 HEMONODE ENLARGEMENT (HEMAL LYMPH NODE)

A lymphoproliferative condition associated with hemonode enlargement and some generalized lymphadenopathy has been described for cattle infected with a lentivirus[321] that is now called *bovine immunodeficiency virus* (BIV). BIV belongs in the genus *Lentivirus,* subfamily Orthoretrovirinae, and family Retroviridae. BIV has molecular similarity to human immunodeficiency virus (HIV) and is associated with persistent lymphocytosis, lymphadenopathy, central nervous system (CNS) lesions, progressive weakness, and emaciation.[330] Infected calves may develop enlarged superficial nodes *(hemonodes)*, mainly in the cervical region anterior and dorsal to the prescapular lymph node, over the spine of the scapula, in the paralumbar fossa, and dorsal to the prefemoral lymph node. Lymphocytosis may be related to an increase in B lymphocytes. In utero transmission of BIV has also been documented.[331]

37.32.2 Adult Lymphoma (Bovine Leukemia Virus)

The adult or enzootic form of lymphoma is the most common neoplastic disease of cattle and is associated with BLV infection. Rates of lymphoma in cattle vary considerably, probably reflecting variation in BLV infection rates. In 1978 the U.S. condemnation of carcasses because of lymphoma was reported to be 170 per 100,000 head slaughtered.[332] A high condemnation rate, sometimes exceeding 1%, was reported for slaughtered California dairy cows,[333] and about 1.73% of BLV-infected cattle had lymphoma.[334] The rate of cattle condemnations resulting from lymphoma appears to have increased over time.[333]

37.32.3 Epidemiology

The epidemiology of adult lymphoma is not completely understood. Herd size might be positively correlated with a high rate of lymphoma, which may reflect higher rates of BLV infection in large herds or a preponderance of susceptible pedigrees in some of the herds studied.[334,335] Susceptibility to BLV infection is

associated with BoLA type,[336,337] which may explain why higher rates of lymphoma are found in certain families of cattle. The progression of disease to lymphocytosis in some BLV-infected cows may also be influenced by BoLA type, suggesting a possible genetic predisposition to development of lymphoma through the antigens of the major histocompatibility complex (MHC) encoded at closely linked loci. Other potentially contributing factors, including nutrition, concurrent infections, and environmental/meteorologic stressors, have not been explored sufficiently. There is no evidence for a seasonally associated pattern to appearance of clinical lymphoma.[333] Antigenic and molecular evidence for the presence of BLV in mammary glandular epithelium has been demonstrated.[338] The effect of persistent mammary BLV infection on the mammary gland is not completely understood. Although one study identified increased average milk production in BLV-infected versus uninfected cattle,[339] others report negative associations between milk production and BLV status.[340,341]

37.32.4 Economics

The economic importance of adult lymphoma varies according to production type.[341,342] Producers incur losses from lymphoma associated with death of cattle (particularly genetically valuable livestock), loss of milk production, costs of treatment and diagnosis, and premature replacement costs for cattle dying or culled as a result of lymphoma. The latter may partly explain an observed increased rate of culling found for BLV-infected dairy cattle.[339,343] In addition to premature culling and replacement, losses are incurred because of failure to retain salvage value of cows condemned for lymphoma at slaughter.[333] A hidden cost of lymphoma also may be in the perpetuation of BLV-infected cattle through in utero infection of calves born to cows with lymphoma.[344,345]

37.32.5 Diagnosis

Cattle presented with the adult or enzootic form of lymphoma usually are older than 4 years but may be as young as 2 years. Cattle are often presented with a history of loss in condition, an abrupt drop in milk production (over a few days), enlarged peripheral nodes, exophthalmos, or partial to complete anorexia, particularly with regard to grain or concentrates. Because dry cows are not observed as closely as lactating cows and are not monitored for milk yield, lymphoma is less likely to be recognized until they freshen. Subclinical lymphoma may be diagnosed in cows submitted for routine reproduction examinations; other signs may include diarrhea, ataxia, paresis, ketosis, and infertility.

Physical examination often reveals an organ system failure resulting from tumor involvement. Thoracic auscultation may reveal cardiac dysrhythmia, tachycardia, tachypnea, and hyperpnea. Common sites of lymphoid tumor predilection in adult lymphoma include right atrium, uterus, retrobulbar space, abomasum, and spinal cord (epidural space); involvement of rumen, colon, and kidney is also seen. Dependent, pitting edema is common when cervical or supramammary lymph nodes are involved. Involvement of the intestinal lymphatics is often associated with generalized dependent edema anterior to the udder. Peripheral nodes typically found to be enlarged are the prescapular, femoral, and supramammary nodes. Feces may be scant, pasty, or watery and probably reflects the presence of lesions within the GI tract. Melena may be present in animals with ulceration of the abomasum and lymphoid cell infiltration in the abomasal wall. Rectal palpation can be a useful in cases lacking peripheral node enlargement or exophthalmos. Tumor masses palpated in the abdomen typically are multiple and range in size from only slightly enlarged lymph nodes to massive lesions half a meter in diameter. The internal iliac nodes are involved in most cattle with abdominal tumors.

Tumors tend to be firm but not hard and may feel slightly lobulated. Differentiation by palpation of lymphoma tumors from other masses is highly subjective. Carcinomas tend to be of similar consistency but are seldom larger than 15 cm in diameter and are usually associated with intestinal tissue. Lymph nodes of cows with a carcinoma are not usually enlarged unless a secondary infection is present. Melanomas are generally less than 15 cm in diameter and hard, sometimes with protrusions 1 to 2 cm high along the surface. They usually are not found associated with lymph nodes. Masses of fat necrosis tend to be firm and are usually associated with omental tissue. Internal abscesses are often single and associated with the uterus, as a consequence of uterine tear and infection during parturition, or with gluteal muscles of the pelvic ceiling, as a consequence of injection-related infections. Exploratory laparotomy may be indicated as an additional diagnostic tool in difficult cases, particularly in valuable cattle.

The hemogram of cattle with lymphoma often is generally unremarkable. Anemia, characterized as microcytic and hypochromic, may be present in cattle with GI hemorrhage. Fibrinogen levels have been inconsistent in lymphoma, and therefore its measurement may be helpful only in differentiating an abscess. Approximately 30% of cattle with BLV infection develop persistent lifelong lymphocytosis, composed mostly of B cells.[346,347]

Cytology of aspirates of tumors or tumorous nodes may not always be a reliable diagnostic tool, although it can be helpful. Discrimination cannot be made between a normal node responding to an infectious agent and a node involved with neoplastic lymphocytes; in both situations, cells resembling young, poorly differentiated lymphocytes may be present. Examination of nontumorous active lymph nodes may reveal an elevated proportion of large, young lymphocytes that could resemble those of lymphosarcoma. Histopathologic examination of biopsied tumors or nodes may be more useful than aspirates in making a diagnosis. However, cytology and culture of aspirates could be helpful in differentiating a tumor from an abscess. Failed attempts at collection of cerebrospinal (lumbosacral) fluid in cattle with recumbency or hindlimb weakness may be associated with the presence of lymphoid tumors in the vertebral canal; cytologic examination of cells from the collection needle in such cases may reveal abnormal lymphoid cells.

Standard serologic testing for BLV involves identification of antibody against the 51-kilodalton (kD) envelope glycoprotein (gp51). Although BLV diagnosis historically involved the use of the agar gel immunodiffusion (AGID) test, that method has been shown to be less sensitive than the enzyme-linked immunosorbent assay (ELISA).[348] ELISA test kits are available commercially that detect antibodies to gp51 in serum and milk.[*] Diagnosis is also possible by use of PCR to detect BLV nucleic acid,[349–351] as well as by a combined PCR-ELISA that is more sensitive than staining of PCR amplicons with ethidium bromide.[352] ELISA-positive cattle that were not detected by PCR testing have been reported, most likely related to a low number of infected circulating lymphocytes at sample collection.[353] The PCR by itself is considered unreliable for routine detection of BLV in herds with a high prevalence of disease.[354] The ability of PCR to detect a BLV infected animal is improved by means of a nested PCR, which was reported to be effective in diagnosing infection when seroconversion had not yet occurred.[355] The presence of antibodies to gp51 is generally considered to be a prerequisite to a diagnosis of lymphoma, except for cows during the periparturient period, when circulating antibodies may fall below the level detectable by a serologic test.[356] The mere presence of BLV antibodies does not necessarily mean that an animal has lymphoma, which is found in only about 1.7% of BLV-infected cattle.[357] However, serology can be helpful in predicting the chance of lymphoma in cattle seropositive to the gp51 antigen. Sera from cattle with lymphoma generally have high titers to the gp51 antigen (score of 3 or 4 on AGID), compared with those of infected cattle without lymphoma (score of 1 or 2). In addition, cattle that do not have lymphoma tend not to have antibodies to the p24 antigen of BLV, as detected by AGID. The percentage of cattle with histologically confirmed lymphoma but in which lymphoma was not diagnosed by a

gp51-positive and p24-negative test result (false-negative rate of diagnostic test) has been found to be only 0.21%, using the AGID test.[334] Unfortunately, most diagnostic laboratories do not have the capability to perform the test using the p24 antigen.

At necropsy, tumors are found enclosed in a capsular-like tissue that, when sectioned with a knife, results in an eversion of tumor stroma. Cut tumor tissue is cream colored and friable, with little binding structure. Centers of tumors may appear necrotic and mushy, whereas peripheral regions are firmer and pink to white. Histopathology provides the only definitive diagnosis. Tissue should be biopsied by surgical removal of as much of the node (or mass) as possible.

* HerdChek Bovine Leukemia Virus Antibody Test Kits (IDEXX Laboratories, Westbrook, Maine); Bovine Leukemia Virus Antibody Test Kit, ELISA (VMRD, Pullman, Wash); SVANOVIR BLV gp51-Ab ELISA (Svanova Biotech AB, Uppsala, Sweden).

37.32.6 Control

No curative treatment for lymphoma exists. However, supportive therapy may be indicated to reduce discomfort and prolong life long enough to remove valuable ova/embryos or calves or to harvest semen.

Until more information is available on the epidemiology of lymphoma, control and eradication hinge on success of efforts to eradicate BLV from a herd. Presently, no vaccines offer effective protection from BLV infection.[358–361] Control and eradication of BLV require reduction of blood transmission through iatrogenic means and through physical contact among cattle.[362] Transmission associated with physical contact between infected and susceptible cattle can be reduced by segregating infected and noninfected cattle.[363–365] Separation of cattle by 10 feet is preferred, but a single fence may reduce sufficiently the degree of contact necessary for transmission. Transmission after physical contact may be through inhalation of BLV shed in nasal secretions.[366–369] Experimental studies have found that under extreme conditions of blood contamination and mucosal irritation, BLV can be transmitted rectally.[370–374] Under conditions typical of routine palpation during pregnancy examination, however, BLV appearance may not necessarily be transmitted to any measurable degree.[372,374] If potential for rectal transmission is a concern, palpation sleeves may be rinsed or replaced between cows. Although insect transmission of BLV is theoretically possible,[375] as demonstrated experimentally by interrupted feeding of tabanids from cattle with persistent lymphocytosis to uninfected cattle,[376] studies of natural infection have not been able to link flies with new natural infections.[377,378] Several studies have been unable to demonstrate transmission after use of a common needle.[379–381] However, infection after use of a Tb needle dipped in blood of a BLV-infected animal could be prevented by wiping the needle with cotton before injection.[382] Although data have not shown the use of common needles to be an important means of BLV transmission, it would be prudent to use individual sterile needles for treatment, testing, or vaccination.

Transmission of BLV has not been shown in cows inseminated artificially using commercially prepared frozen semen.[383–387] However, infection resulting from the use of an infected bull in natural breeding may be possible.[388–390] Semen of 27 bulls that were BLV PCR positive in peripheral blood had no evidence BLV on PCR.[391] Embryo transfer recipients should be tested for BLV before transfer.[392] Embryo transfer using noninfected recipients offers a means of producing phenotypically preferred cattle from BLV-infected cows and controlling in utero infection,[377,383,393,394] because at harvesting, embryos are not infected.[385] It is possible to produce

transferable in vitro fertilized embryos that are free of BLV provirus from oocytes that are exposed to BLV during maturation, fertilization, or after fertilization, through a washing procedure.[395]

For most herds, control and eradication of the infection would require modification of facilities, alteration of management practices, and serologic surveillance at least annually. Planning a control program should include a cost/benefit analysis to evaluate potential return on the investment. Financial benefit of a BLV control program has been documented in herds in which the prevalence of BLV infection is 12.5% or higher.[396] The selective culling of BLV-infected cattle based on positive lymphocyte BLV antigen expression in vitro was reported to be effective in preventing transmission of BLV infection.[397]

37.33 LYMPHOMA IN HORSES

MONICA ALEMAN

Lymphoma and lymphosarcoma are terms that have been used interchangeably to describe a group of neoplasias originating from the lymphoid system, including nodal lymphoma (lymph nodes) or extranodal lymphoma (thymus, spleen, and mucosal-, conjunctival-, or skin-associated lymphoid tissue [MALT, CALT, and SALT, respectively]). The mucosal-associated lymphoid tissue includes mucous membranes lining the digestive, respiratory, and urogenital systems. Metastasis can occur to other organs, including primary lymphoid tissues such as bone marrow. Based on its embryologic origin, lymphoma is classified as a *mesenchymal neoplasm*. Although the suffix *-oma* indicates a benign neoplasm and *-sarcoma* a malignant mesenchymal neoplasm, the Leukemia and Lymphoma Society determined that lymphoma is the appropriate term because all neoplasms of the lymphatic system in humans are malignant. In veterinary medicine, lymphomas are also malignant, so the term *lymphoma* has been adopted. It is important to emphasize that "lymphoid hyperplasia" is not synonymous with lymphoma. Clonality studies may determine if a specific clone of lymphocytes (B, T, natural killer, and plasma cells) are malignant versus hyperreactive.

Lymphoma is one of the most common malignant neoplasia in the horse. On postmortem examination, prevalence of lymphoma in the horse was estimated to be 2% to 5%.[398,399] In contrast to other species, lymphoma development has not been associated with a viral etiology in the horse. However, virus-like particles in lymph nodes of neonatal foals with lymphoma have been described, although no causal relationship was proved.[400,401] Lymphomas can occur at any age, from an aborted equine fetus to horses 30 years old.[401–403] Typically, age of onset of all forms of lymphomas has been reported as 5 to 10 years; however, a recent study revealed that the mean age of intestinal lymphoma was 16 years.[403,404] There is no apparent breed or gender predilection. The clinical signs vary depending on tumor location but most often include lymphadenopathy, lethargy, weight loss, edema, and pyrexia. Affected lymph nodes tend to be firm, cool, and nonpainful. In one retrospective study of 79 horses with lymphoma, 21 cases had ocular involvement.[405] Paraneoplastic pruritus and alopecia were described in a horse with diffuse lymphoma.[406] Neurologic alterations, lameness, osteolysis, and pathologic fractures have been described as the result of lymphoma.[407–412]

1176
1177

The hematologic features of lymphoma are varied. However, anemia is a relatively common finding. Anemia is thought to be caused by suppression of erythropoiesis, bone marrow infiltration, blood loss, or immune-mediated hemolytic anemia.[81] There is only one report, in a 9-year-old warmblood mare, involving multicentric lymphoma and persistent paraneoplastic erythrocytosis.[308] Frank leukemia is rare, but when present (reported counts as high as 256,500 cells/μL), neoplastic cells are generally found in the bone marrow.[413] More often the lymphocyte count is within the reference range or low. Atypical lymphocytes may be noted in the blood smears of 20% to

50% of affected horses, especially late in the course of disease.[414–417] A modest neutrophilic leukocytosis with an elevated fibrinogen is often seen. This inflammatory response can cause confusion when trying to differentiate neoplasia from internal abscessation.[418] Serum biochemistry profiles may show internal organ involvement. Serum protein alterations are frequently observed and include hypoalbuminemia, hyperglobulinemia with polyclonal gammopathy (most cases), and decreased albumin/globulin ratio. However, deficiencies in IgG and IgA concentrations were reported in a horse.[419] Neoplastic lymphocytes may arise from reactive B-cell clones producing antibodies responsible for gammopathies and immune-mediated processes (hemolytic anemia, neutropenia, lymphopenia, thrombocytopenia).[81] Although low serum IgM concentrations and hypercalcemia have been reported in a few cases, these are not consistent features of lymphoma in the horse.[179,417,419–421]

Lymphomas in horses have been classified based on anatomic distribution, morphology, and cell lineage.[422–425] Based on its anatomic distribution, the classification of lymphoma in the horse is as follows: multicentric, generalized, alimentary or intestinal, splenic, mediastinal, thymic, and cutaneous forms. The spleen is the organ most frequently affected with lymphoma, and lymphoma is the most common neoplasia of the spleen.[426]

Morphologically, lymphocytes are classified as “small” if their nuclear diameters are 1.5 times or less the diameter of erythrocytes and “large” if their nuclei average twice or more the diameter of erythrocytes.[423] Small-cell lymphoma consists of 60% or more small cells. Large-cell lymphoma consists of 60% or more large cells. A lymphoma designated as “mixed” is a tumor that contains both small and large neoplastic cells of the same immunophenotype.[423]

Immunohistochemical classification of lymphomas has been determined by using monoclonal antibodies, such as BLA36, CD79a (mb-1), and B29 for B-cell lymphomas and polyclonal antibodies to CD3 and CD5 for T-cell lymphomas. All three lymphomas—B cell, T cell, and mixed B and T cell—have been reported in the horse.[423,424] The monoclonal antibody proliferating-cell nuclear antigen (PCNA) has been used to determine the proliferative status of the cells.[423] Frequently, lymphomas are described as T-cell—rich B-cell lymphoma, or vice versa. T-cell—rich, large—B-cell lymphoma is a neoplastic proliferation of large B cells associated with a prominent component of nonneoplastic reactive T lymphocytes that constitutes a significant percentage of the cellular population.[423] The presence of large numbers of nonneoplastic T cells within a B-cell lymphoma could result in an erroneous diagnosis of a T-cell tumor. Neoplastic cells are determined based on large cell size; large, vesicular, and irregularly shaped nuclei with coarse chromatin; atypical mitotic figures; and positive immunostaining to PCNA markers. Nonneoplastic cells are identified by their normal morphology and lack of immunoreactivity to proliferation markers. However, it may not be this simple to differentiate accurately between neoplasia and reactive inflammatory response; clonality assays are required to make this determination. Polyclonality is seen with lymphocytic hyperplasia and monoclonality with lymphoma. Accurate characterization and staging of lymphomas in humans have been critical to establish therapeutic management and prognosis. All forms of lymphomas are considered malignant in the horse.[426]

37.33.1 Multicentric Lymphoma

The multicentric form of lymphoma involves lymph nodes (veterinary oncology terminology: nodal = lymph node; multiple lymph nodes = multinodal = multicentric) regardless of location.[426] Extranodal lymphoid tissue (lymphoid tissue other than lymph nodes) is not involved.[426] However, multicentric lymphoma may metastasize to extranodal areas, in which case it will be classified as generalized (diffuse) lymphoma.[426] In veterinary medicine the terms *multicentric* and *generalized* have been used interchangeably.

37.33.2 Generalized Lymphoma

The generalized form is considered an end-stage lymphoma characterized by involvement of both nodal and extranodal lymphoid tissue.[426] This form is more common than the intestinal (extranodal) and mediastinal (nodal) forms alone. Horses often present with severe lethargy, emaciation, anorexia, generalized lymphadenopathy, and edema because of impaired lymphatic drainage.[404,427] Anemia is common, and hypoproteinemia caused by hypoalbuminemia may be found. Although rare, leukemia is generally associated with this form of lymphoma.[413] In addition to lymphoid tissue involvement, infiltration of tumoral cells has been reported in the spleen, liver, bladder, kidney, lung, heart, nasopharynx, eye, ovary, uterus, brain, and spinal cord.[402,413,420] Multifocal eosinophilic granulomas have been identified in neoplastic lymph nodes, thought to be in response to paraneoplastic interleukin-5 (IL-5) and granulocyte-monocyte colony-stimulating factor (GM-CSF) produced by neoplastic cells.[413]

37.33.3 Alimentary or Intestinal Lymphoma

Alimentary tract lymphoma involves the GI tract, more frequently the small intestine.[424,428] Lymphoma is the most common neoplasia of the intestinal tract in horses.[403] This neoplasia has been reported most often in horses less than 5 years of age. However, a recent retrospective study on intestinal neoplasias revealed that the mean age of horses with lymphoma was 16 years (range, 2 to 30 years), with Arabian horses the most common breed associated with this type of lymphoma.[403] Lymphoma arises from the lymphocytes of the lamina propria (extranodal lymphoid tissue) of the intestinal tract, resulting in diffuse or segmental thickening, focal masses, or scattered crater-like ulcers with raised margins of the intestinal wall.[424,425,428] Lymphadenopathy is generally not present. Metastases to mesenteric lymph nodes, liver, and spleen have been reported.[425] Transabdominal ultrasound may be very useful for the detection of intestinal thickening and cecal lymphadenopathy. These tumors could be of B-cell or T-cell origin. Although most of these tumors are considered to be of B-cell origin, clonality assays recently revealed that T-cell lymphomas are more common than B-cell lymphomas in the intestinal tract.[403] This neoplasia is usually associated with malabsorption, protein-losing enteropathy (hypoalbuminemia), weight loss, edema, abdominal effusion, mild recurrent colic, and diarrhea.[428–431] Affected horses frequently have an abnormal glucose or xylose absorption test, indicating small intestinal malabsorption. Taylor et al.[403] reported that abdominal fluid cytologic analysis was useful for diagnosis of miscellaneous intestinal neoplasia in 38% of cases.

1177 1178

37.33.4 Thoracic Lymphoma: Mediastinal/Thymic

Lymphoma is the most common thoracic neoplasia in horses and may involve mediastinal lymph nodes, thymus, and lungs.[432,433] Exclusive involvement of mediastinal lymph nodes is called *mediastinal lymphoma,* whereas exclusive involvement of thymus is called *thymic lymphoma*.[426] Prevalence varies from 18% to 29% of all forms of lymphoma.[110,430,434] Primary and secondary (metastatic) mediastinal lymphomas have been reported. Most often, however, the neoplasia results from metastasis.[432] Primary mediastinal lymphoma is usually seen in adult horses (mean age of 10 years, range of 2 to 30 years), although it was reported in a 1-month-old foal with a 1-week history of respiratory distress.[402] Metastasis from primary mediastinal lymphoma often occurs. In the early stages of the disease, minimal clinical signs may be observed. Common signs include

nasal discharge, adventitious lung sounds, pleural effusion, thoracic ventral and limb edema, and regional lymphadenopathy at the thoracic inlet.[430,432] Other signs include cough, pyrexia, pleurodynia, and in some cases, respiratory distress.[432,435] Temperature, pulse, and respiratory rate are often elevated. Dysphagia may be observed in some cases with retropharyngeal lymphadenopathy.[436] High nucleated cells counts of several thousand per microliter, with a large percentage of abnormal lymphocytes, are often evident on pleural fluid cytology; however, collection of multiple pleural fluid samples may be necessary to establish a definitive diagnosis.[435] Some of the cytologic abnormalities include the presence of prolymphocytes, lymphoblasts, nuclear blebbing, indented and cleaved nuclei, amorphous nuclei, altered nuclei/cytoplasm ratio, and mitotic figures.[435] Lymphomas could be of B-, T-, or mixed-cell origin, but T-cell lymphomas are more common.[423,435]

37.33.5 Cutaneous Lymphoma

Cutaneous tumors are confined to the skin-associated lymphoid tissue. Single or multiple, subcutaneous, firm, nonpainful nodules ranging from less than 1 cm to greater than 20 cm in diameter can develop rapidly or slowly, regionally, or over most of the body surface.[437,438] The nodules are usually covered with hair. In some cases the lesions tend to wax and wane spontaneously, or they are associated with hormonal influences, seasonality, and steroid therapy. There is one report of complete regression of cutaneous lymphoma after surgical removal of an ovarian tumor.[439] Because of the waxing and waning response, there is controversy whether this may be lymphoid hyperplasia rather than lymphoma. Depending on anatomic location, lymphomas may cause mechanical lameness and limb edema as a result of vascular and lymphatic obstruction. In most cases, no hematologic abnormalities are present, and generalized lymphadenopathy and internal organ involvement are rare. This type of tumor is usually of B-cell origin. Mycosis fungoides is another form of cutaneous lymphoma in which there is diffuse infiltration of neoplastic T-cell lymphocytes in the epidermis, dermis, and subdermis. This type of lymphoma has been reported in a mare with a vulvar mass that infiltrated the skin of the perineum and ventral abdomen.[440] Cutaneous lymphoma may involve mucocutaneous junctions and carries a poor prognosis if deeper tissues are involved.[440]

37.33.6 Angiotrophic Lymphoma

Also known as *endotheliotrophic lymphoma* and *intravascular lymphangiomatosis,* angiotrophic lymphoma has been described in humans, dogs, and cats.[441–443] There is a single report in horses, in a 12-year-old pregnant thoroughbred mare with anorexia, tachycardia, and mild fever.[444] The significant laboratory abnormalities were profound anemia (PCV of 12%), decreased RBC count, marked anisocytosis, mild lymphopenia, low IgM, and marked erythroid hyperplasia and erythrophagocytosis on bone marrow biopsy. Triglycerides, cholesterol, and total bilirubin were elevated on serum biochemistry. Coombs' and Coggins' tests were negative. Postmortem examination revealed generalized icterus, with moderately enlarged mediastinal and mesenteric lymph nodes. Histologic examination revealed thickened pulmonary alveolar septa and vessels crowded with atypical lymphoid cells with scattered mitoses. Similar atypical cells were evident in renal vessels. The neoplastic cells were determined to be of T-cell origin based on immunohistochemical staining. Angiotrophic lymphoma may represent an antemortem diagnostic challenge because of the lack of circulating neoplastic lymphocytes and identifiable masses.

37.33.7 Chemotherapy for Treatment of Lymphoma

Information about chemotherapy for lymphoma in horses is limited. One protocol used in two pregnant mares with lymphoproliferative disease consisted of a combination of cytarabine (200 to 300 mg/m^2 SC or IM every 7 to 14 days), chlorambucil (20 mg/m^2 PO every 14 days) or cyclophosphamide (200 mg/m^2 IV every 14 to 21 days), and prednisolone (1.1 to 2.2 mg/kg PO every 48 hours).[445] Vincristine (0.5 mg/m^2 IV every 7 days) can be added if no clinical improvement is noticed in the first month of therapy. This protocol was continued for 2 to 3 months, followed by a maintenance protocol consisting of gradual decreases of prednisolone, and extending by 1 week the administration of other chemotherapeutic agents, for the next 2 to 3 months. This was followed by extending the administration interval by another week for 2 to 3 months, for a total of 6 to 9 months.[445] Other protocols include drugs used alone or in combination, such as L-asparaginase (10,000 to 40,000 U/m^2 IM every 14 to 21 days), doxorubicin (50 mg/m^2 IV), vincristine (1.4 mg/m^2 IV), and rituximab (375 mg/m^2 IV). A horse with thoracic lymphoma was treated with cytarabine (170 mg/m^2 IM) 2 weeks apart, alternating with cyclophosphamide (142 mg/m^2 IV) 7 days after each dosage of cytarabine.[435] In addition, the horse received prednisolone (86 mg/m^2 PO every 48 hours) and was discharged 1 month after the initiation of chemotherapy, with instructions to continue prednisolone at the previous dosage for life. Eight months after discharge, the horse was in good health and resumed light exercise. Therapy may be attempted with dexamethasone (0.2 mg/kg IV or PO every 24 hours for 5 days), followed by prednisolone (1 to 2 mg/kg PO every 24 hours). Tapering dosages of corticosteroids is not recommended because this has no therapeutic benefit and may induce drug resistance to corticosteroids and chemotherapy.[426]

Complications associated with chemotherapeutic agents in horses include anorexia, lethargy, thrombosis, arrhythmias, laminitis, bone marrow damage, GI and genitourinary toxicoses, urticaria, and immunosuppression. Anemia, thrombocytopenia, leukopenia, and secondary infections may occur.[446] Successful management of cutaneous lymphomas has been achieved using glucocorticoids such as dexamethasone, prednisolone, and betamethasone. As mentioned earlier, however, controversy surrounds the nature of cutaneous nodules as possible lymphoid hyperplasia and not true lymphomas. Other treatments include autologous tumor vaccine and radiation therapy.[447,448] Although periods of remission have been reported with chemotherapy,[435,445] the long-term prognosis has been poor for most horses.

1178 1179

37.34 LYMPHOMA IN NEW WORLD CAMELIDS

MONICA ALEMAN

Lymphoma is the most common neoplasia in New World camelids. Two forms of lymphoma, multicentric and generalized, have been reported in alpacas and llamas.[449–456] There is no age or gender predisposition. The reported median age of affected alpacas was 0.8 year, with a range of 0.2 to 2 years.[456] The median age of affected llamas was 5.5 years, with a range of 0.3 to 15 years.[456] However, information from approximately 50 camelids with lymphoma (unreported and reported) revealed a mean age of 4 months and 4 years for alpacas and llamas, respectively.[457] Lymphoma has been diagnosed in alpacas as early as a fetus and 2-week-old cria.[457] The pathogenesis of lymphoma in camelids is unknown at present.

The most common clinical signs are weight loss, palpable masses, lethargy, respiratory signs, and anorexia.[449–453] Other signs are tachycardia, fever, weakness, and recumbency if the CNS is affected.[451,456] The most common clinicopathologic abnormalities include anemia, left-shifted leukogram, hypoalbuminemia, and hyperglycemia. Cerebrospinal fluid (CSF) analysis may yield atypical, immature lymphocytes if the CNS is involved.[456] Liver, kidney, heart, bone marrow, lymph nodes, stomach, and nervous system (extradural and subarachnoid spaces) have been reported to be involved.[449–453,456] Immunophenotyping analysis has been limited to three alpacas; two had T-cell and one had mixed B-cell and T-cell lymphoma.[452,456] Treatment of lymphoma was attempted in a single case but was unsuccessful.[451]

37.35 LEUKEMIA IN HORSES

MONICA ALEMAN

Leukemia is a rare neoplasia of the hematopoietic system that originates from the bone marrow (primary leukemia).[310] A leukemic phase (secondary leukemia) has been rarely reported in horses with lymphoma, in which blood and bone marrow were infiltrated with neoplastic cells.[310,413,415,416] Based on cell of origin, the major forms of leukemia include myeloid and lymphoid leukemias, which can have an acute or chronic clinical course. According to the Leukemia and Lymphoma Society, *acute* leukemias are rapidly progressing disorders that affect mostly primitive or immature cells that lack normal function; whereas *chronic* leukemias progress slowly, allowing some growth and cell maturation, which may preserve limited normal function. Reported leukemias in the horse include myelomonocytic, monocytic, granulocytic, eosinophilic, and lymphocytic forms.[76–79,413,415,458–472] Based on presence and numbers of cells in blood, other terms used are leukemic, subleukemic, and aleukemic leukemias. *Leukemic* leukemia is characterized by an increase in cell numbers in peripheral blood. *Subleukemic* leukemia is defined by an increase in abnormal blast cells in blood, with a total white blood cell (WBC) count within the reference range or low. *Aleukemic* leukemia is characterized by abnormal cells in the bone marrow, but not in peripheral blood.

There is no apparent breed or gender predisposition based on the few reported cases and horses seen at the University of California, Davis.[76–79,413,415,458–472] The age at onset of clinical signs ranges from 2 to 25 years. The most common clinical signs are weight loss, lethargy, anorexia, pyrexia, and lymphadenopathy if associated with lymphoma. Other signs are weakness, ventral edema, exercise intolerance, colic, and recurrent or concurrent infections.

At the initial stages of the disease, the laboratory features may show mild hematologic abnormalities, including one or more of the following: anemia, neutropenia, lymphopenia, thrombocytopenia, hyperproteinemia, and hyperfibrinogenemia. As the disease progresses (days to months), marked leukocytosis (counts up to 270,000 WBCs/μL) and hyperproteinemia will be observed in leukemic leukemias.[413] Thrombocytopenia is a common hematologic feature.[413,468,469,472] Pancytopenia and high blast cell counts (up to 1.6×10^9 cells/μL) were reported in a lactating mare with myeloblastic leukemia.[472] Pancytopenia caused by severe infiltration of leukemic cells in the bone marrow, ineffective hematopoiesis, and myelofibrosis have been reported.[468] Horses with multicentric lymphoma, pancytopenia, severe leukocytosis (more than expected for severe inflammation), or presence of atypical or blast cells in peripheral blood should prompt the collection of a bone marrow aspirate or biopsy. Bone marrow aspirates may have normal to altered myeloid/erythroid ratio (reference range, 0.5 to 3.76), with a

disproportionate number of atypical or poorly differentiated blast or mature cells of certain lineage. A decrease in or absence of megakaryocytes is often observed.

Hyperproteinemia is a consistent finding because of hyperglobulinemia. Serum electrophoresis typically shows a polyclonal increase of β_2- and γ-globulin fractions, and in some cases α-globulin fraction as well. Marked increases in serum IgG and IgA concentrations have been detected in horses with lymphocytic leukemias.[413] Deficiencies in IgA and IgM have been reported in a single horse with chronic lymphocytic leukemia.[465]

Necropsy findings may include mucosal ulceration, edema, thrombosis, and hemorrhages of various organs resulting from intravascular leukostasis (aggregates of leukemic cells in blood vessels), disseminated intravascular coagulopathy, and thrombocytopenia secondary to decreased production of megakaryocytes. Leukemic-induced cell lysis may occur as the result of mediators released by neoplastic cells. Peripheral and internal lymphadenopathy may also be observed. Other pathologic findings are those associated with concurrent disease.

The diagnosis is based on routine blood work, cytologic and histopathologic evaluation of bone marrow, immunocytochemical analysis, flow cytometry, and immunophenotyping.[310] Previously, leukemic cells in peripheral blood and bone marrow were described based on their morphology; however, this may result in leukemia misclassification, especially in acute leukemias, in which mononuclear blast cells constitute the leukemic clone, which may lack specific identifying morphologic features. Numerous cytologic and cytochemical stains have been used to determine the type of leukemia, such as Wright, Giemsa, Sudan black B, peroxidase, periodic acid—Schiff, alkaline phosphatase, acid phosphatase, various esterases, and surface glycoproteins. However, leukemic cells may also lack specific cytochemical properties. Currently, the various types of leukemias are determined by the identification of specific cellular antigens using a panel of monoclonal antibodies and flow cytometry in peripheral blood and bone marrow; examples are B-cell/IgM-positive, B-cell/IgM-negative, CD3/CD4/CD5-positive T-cell, CD3-negative/CD4-positive T-cell, and CD13-positive myeloid leukemias.[413,465,469] Table 37-2 lists the various monoclonal antibodies for specific equine leukocyte antigens.

The prognosis is poor, resulting in death within days to a few months after diagnosis. Treatment of leukemia has been attempted in horses with cytosine arabinoside, cytarabine, and prednisolone, but with little success.[461,469,471] 1179 1180

Table 37-2 Monoclonal Antibodies for Specific Equine Leukocyte Antigens (ELAs)

ELA Marker	Specificity
EqCD2	T cells

37.36 MYELOMA IN HORSES

MONICA ALEMAN

Myeloma is a neoplastic proliferation of plasma cells that primarily originate in the bone marrow but may have an extramedullary source.[473] Both forms have been reported in the horse.[474–476] Accumulations of neoplastic plasma cells outside the marrow is called *extramedullary plasmacytoma*.[473] Plasmacytomas can form in several organs and tissues, including the skin. The most common extraosseous sites in horses are lymph nodes, kidneys, spleen, and liver.[474,476,477] Multiple myeloma involves bone marrow at multiple locations and other tissues; and it is the most common form of myeloma in humans.[478] In human medicine, causes of myeloma include chromosomal translocation, irradiation, and chronic antigenic stimulation.[473]

Myeloma is a rare neoplasia of the horse, with only 16 cases reported in the literature, at a median age of 14 years (range, 3 months to 25 years).[474–477,479–489] Almost half these cases were quarter horses, but various breeds, including draft horses and ponies, were represented. There is no apparent gender predilection. The clinical signs

vary with the degree of plasma cell infiltration, extent, and location. The most common clinical signs are weight loss, anorexia, fever, pale mucous membranes, lethargy, limb edema, and recurrent infections.[474–477,488,489] Bone pain as the result of osteolytic disease is the most common early sign of myeloma in humans.[478] Four horses from the literature were reported to have lytic lesions. The clinical signs in these horses included paresis, cervical pain, and lameness.[476,480,482,485]

The laboratory features are anemia, hyperproteinemia caused by hyperglobulinemia, hypoalbuminemia, and proteinuria. Anemia results from reduced erythropoiesis secondary to myelophthisis and infection, blood loss, and paraproteins' osmotic effect. Pancytopenia is observed if myelophthisis develops. Hypercalcemia has been reported in a few cases.[474,476,477] Exception to these features occurred in one gelding with systemic AL amyloidosis and multiple myeloma.[489] This horse had hypoproteinemia, hypoglobulinemia, hypoalbuminemia, and hypocalcemia; thought to be the result of protein-losing enteropathy caused by the severe, diffuse gastrointestinal amyloidosis.[489] Concurrent systemic amyloidosis and multiple myeloma are common in humans but extremely rare in domestic animals, with only one cat and one horse reported in the literature.[489,490] Serum parathyroid hormone—related protein concentration was mildly elevated in one horse with multiple myeloma.[477]

In secretory myelomas the neoplastic plasma cells are responsible for overproduction of a monoclonal immunoglobulin called M protein, or paraprotein. M protein may be fragments (mainly light chains, also called Bence Jones protein) or a complete immunoglobulin. Subclasses of IgG are the predominant paraprotein associated with myeloma in horses.[474,488] Recently, however, three horses were reported to have IgA paraprotein.[476,477]

Plasma cells are relatively sparse in normal bone marrow. The involvement of the marrow is usually focal rather than diffuse, requiring multiple marrow aspirates in some cases to confirm plasmacytosis. The diagnosis of multiple myeloma in humans is based on the presence of at least 10% of plasma cells in the affected tissue, monoclonal protein in serum or urine, and evidence of end-organ damage (hypercalcemia, renal insufficiency, anemia, or bone lesions). Renal insufficiency has not been reported in horses with myeloma.[474,476] Bleeding and blood hyperviscosity syndrome are common complications of multiple myeloma in humans[478]; these complications have been reported in four horses.[474,483] In addition, bone nuclear scan studies have been helpful in humans to detect single (monostotic) versus multiple (polyostotic) myeloma.

Median survival after diagnosis in humans is approximately 3 years.[478] Because of poor prognosis or deterioration, most reported horses were euthanized within a few days to months after diagnosis. However, two horses survived for 1 and 2 years, respectively.[484,487] A quarter horse with multiple myeloma was euthanized at age 29 years, 3.5 years after diagnosis, because of deterioration.[476] This horse had weight loss, intermittent limb and ventral edema, recurrent infections, and colic. Serial blood work revealed mild anemia, hyperproteinemia, hyperglobulinemia, hypoalbuminemia, hypercalcemia, and hyperproteinuria.

37.37 LYMPHANGIOMA IN HORSES

MONICA ALEMAN

Lymphangioma is a rare tumor in horses that originates from lymphatic vessels. Morphologically, lymphangiomas are classified into three types: simplex or capillary, cavernous, and cystic.[491] This neoplasia has been described involving cutaneous tissue of the mammary gland, thigh and inguinal regions, pleural cavity, and intestines.[492–

[494] Lymphangioma has only been observed in young horses. The clinical signs vary depending on tumor location. Because of the extent of these tumors, surgical removal has not been possible, resulting in euthanasia.

37.38 OTHER DISEASES OF THE HEMOLYMPHATIC SYSTEM

37.38.1 ANTHRAX

RICHARD L. WALKER

Anthrax is a soil-borne bacterial disease primarily affecting herbivores. It most often presents as an acute septicemia with high mortality. Other animal species, including humans, can be infected. Anthrax occurs worldwide and is noteworthy because of its impact on agriculture and its potential to cause zoonotic infections. The anthrax bacillus has recently garnered increased attention because it is one of the microbes most likely to be used as a bioterrorism agent.

1180
1181

37.38.2 Etiology

Bacillus anthracis is the etiologic agent of anthrax. In the vegetative form, it is a large, rectangular-shaped, gram-positive rod. Vegetative cells are predominantly found in tissues of infected animals; however, *B. anthracis* exchanges genetic information with other *Bacillus* species in the environment, indicating vegetative cells exist, to some extent, outside animal hosts.[495] Under nutritionally limiting conditions, vegetative cells are induced to form spores. Sporulation is an oxygen-dependent process and does not occur under anaerobic conditions. The spore form of *B. anthracis* is highly stable and resists many chemical and heat treatments, as well as adverse environmental conditions.[496] Spores can survive and remain infectious in the environment for decades.

37.38.3 Pathogenesis

Exposure of animals occurs primarily from grazing contaminated pastures and ingesting spores.[497] Fodder grown in contaminated soil and contaminated animal by-products are other sources for infection. In swine, consumption of contaminated animal by-products in feed is the usual source of infection.

Ingested anthrax spores cross mucosal barriers, are phagocytosed by macrophages, and are transported to regional lymph nodes. As spores convert to their vegetative phase, they are able to avoid the antimicrobial action of the phagocyte and escape into the extracellular environment. The production of plasmid-encoded virulence factors, particularly a poly-D-glutamic acid capsule and a three-component toxin, are key to survival in the host.[497] Production of a capsule is important in evasion of the host's phagocytic defenses. The three components of the toxin are protective antigen (PA), lethal factor (LF), and edema factor (EF). PA attaches to host cells through surface receptors, polymerizes to form a prepore, and binds one or both of the other two toxin components, LF and EF. This entire complex enters the cell by endocytosis. In the endosome the polymerized prepore becomes a functional pore and allows LF and EF to enter the host cytoplasm.[498] The enzymatic effects of EF and LF disrupt host cell functions, including innate and adaptive immune responses.[499] EF increases cyclic adenosine monophosphate (cAMP), leading to tissue edema and suppression of phagocytic capability. LF causes cell death through interruption of signal transduction pathways and increases numerous proinflammatory

cytokines. The result is rapid proliferation of *B. anthracis* in the host and an overwhelming septicemia. Death is caused by toxic shock with hypotension and multiorgan failure.

37.38.4 Epidemiology

As mentioned, anthrax occurs worldwide, and frequency of outbreaks depends on geographic location. Some parts of the world (sub-Saharan Africa, central and southern Asia), with high concentrations of spores in the soil are referred to as "anthrax zones." In the United States, certain states or geographic regions, such as Texas and the plains regions, have more occurrences of anthrax than other areas. Some areas with greater incidence of disease follow old cattle trails, which may have been the primary source for contaminating those environments.[500,501]

Environments favorable for anthrax spores include soils with elevated pH and concentrations of selected cations (Ca^{++}, Mn^{++}) and soils rich in organic material.[497] Droughts followed by heavy rainfall or flooding often precede outbreaks, as do earth-disturbing activities such as excavations. Topography that favors collection of runoff and establishment of temporary water storage areas (seasonal ponds) may promote the concentration of spores.[500,501] Outbreaks usually occur during warmer months of the year.

Bites from bloodsucking insects can spread anthrax organisms from infected septicemic animals through mechanical transmission.[502] Scavenging animals can also disseminate organisms.[501] Carcasses of affected wildlife are an additional source for contaminating environments because they are unlikely to be disposed of properly.

37.38.5 Clinical Presentation

Susceptibility to *B. anthracis* infection depends on the individual animal species. Ruminants (cattle, sheep, and goats) are most susceptible. Because of the often peracute nature of anthrax in ruminants, clinical signs before death may not be observed. If seen, nonspecific clinical signs include fever, depression, respiratory distress, congestion of mucous membranes, and convulsions.[503] In more protracted cases, bloody diarrhea, hematuria, and localized tissue swelling may be observed.

Horses develop an acute intestinal form of anthrax. Associated clinical signs include colic, diarrhea, fever, and depression followed by a fatal septicemia. A more localized form, possibly initiated by insect transmission, typically involves the neck region with massive edema. A dependent edema may result involving the thorax, abdomen, prepuce, or mammary gland.

SWINE are less susceptible to anthrax infection. Oropharyngeal involvement with swelling of the head and neck is the most common presentation.[497] If severe enough, edematous tissue may obstruct breathing and swallowing. Cervical lymph nodes are prominently involved. An intestinal form may present as dysentery. Pregnant animals may abort.

37.38.6 Pathology

Animals that die of anthrax sometimes produce bloody exudates from body orifices and show incomplete rigor mortis. Blood is poorly clotted. Carcasses undergo rapid decomposition. If a carcass is opened, the spleen is frequently enlarged and has a "blackberry jam" consistency. Lymph nodes may be edematous and hemorrhagic. Hemorrhages may be present on the surface of other organs. Signs of enteritis may be apparent. The more

localized edematous form shows regional swelling. In the oropharyngeal form the cervical lymph nodes are edematous and hemorrhagic.[503] Histologically, large numbers of bacilli are observed in most tissues of septic animals. Spleen and lymph node architecture is obscured by the massive hemorrhages.

37.38.7 Diagnosis

Initially, anthrax may be confused with clostridial infections, lightning strikes, plant poisoning (e.g., oleander), other intoxications, or mineral deficiencies. Carcasses of animals with suspected anthrax should not be opened, in an effort to prevent sporulation of vegetative cells and further contamination of the environment. Laboratory diagnosis is necessary for definitive diagnosis of index cases. Diagnosis is made by examining direct blood or tissue smears and performing bacteriologic cultures. Samples that minimize the potential for environmental contamination but still provide good-quality cultures include unclotted blood collected from superficial veins and ocular fluid collected in a sterile syringe using a large-gauge needle. An intact eye can also be removed and submitted to the laboratory for diagnostic evaluation. In the more localized form of anthrax, samples from regional lymph nodes may be required. Because anthrax carcasses undergo rapid putrefaction, and vegetative *B. anthracis* cells are destroyed during the putrefactive process, the time between death and sample collection can substantially affect the recovery rate of *B. anthracis*. As a good safety practice, whenever a case of anthrax is suspected, this should be relayed to laboratory personnel performing the diagnostic testing.

1181 1182

Examination of direct smears by Gram stain is performed to demonstrate the typical, large, gram-positive, squareended rods found singly or in chains of two to four cells. A polychrome methylene blue (M'Faydean) capsule stain is performed to demonstrate the presence of the *B. anthracis* capsule surrounding organisms observed in direct smears. Frequently it is necessary to distinguish anthrax bacilli from postmortem invading clostridial species, which have more rounded ends and are acapsular when examined with the M'Faydean stain. *B. anthracis* also stains well with common laboratory stains, including Wright and Giemsa stains, and displays morphology similar to that observed on Gram staining.

Isolation of *B. anthracis* is readily made on standard sheep blood agar. Colonies are apparent after as soon as 6 hours of incubation. Typical *B. anthracis* colonies after 24 hours of incubation are large, gray-white, with a bee's-eye texture. Colonies are usually nonhemolytic. Gram stains of young colonies show very long chains (≥10 cells) of large, square-ended, gram-positive rods often described as having the appearance of a row of “railway boxcars.”

Identification of *B. anthracis* isolates is confirmed by demonstrating lack of motility, lysis by a specific bacteriophage (gamma phage), and protoplast formation in the presence of penicillin (string of pearls test).[504] Capsules are demonstrated in culture by growing isolates on bicarbonate agar under an increased CO_2 atmosphere. Spores develop in cultures after approximately 48 hours of incubation. They are centrally located in the cell and do not cause the cell to bulge.

A number of molecular-based and rapid screening tests for detecting *B. anthracis* directly from samples or for identifying individual isolates are available. Most of these are primarily used in bioterrorism surveillance programs. PCR-based assays using primers specific for the capsule and PA genes are useful for differentiating field strains from the vaccine strain. Because of the sporadic nature of the natural disease, molecular-based identification may not be available in all veterinary diagnostic laboratories.

37.38.8 Treatment, Control and Prevention

Any suspected anthrax case should be reported to appropriate local or state veterinary regulatory officials as soon as possible. Because of the peracute nature of many anthrax infections, successful treatment requires early intervention; however, treatment is often unrewarding. Penicillin and tetracycline remain the drugs of choice for treating animals. Treatment should be continued for a minimum of 5 days. Rare *B. anthracis* strains resistant to these antibiotics have been reported.

Carcass management is critical in controlling anthrax outbreaks. Carcasses should not be opened or moved from the area where they are discovered. Carcasses are destroyed either by burning or deep burial. Burning of carcasses is preferred to burial because it is more effective at destroying spores. Any contaminated bedding or soil should be handled similarly.

In the face of an outbreak, regulatory officials will likely quarantine affected premises. All potentially exposed animals should be closely observed for clinical signs that suggest they might be infected. All clinically normal animals should be vaccinated using a commercially available, live, acapsular vaccine strain (Sterne strain).* Prophylactic antibiotic treatment of unaffected herdmates is sometimes practiced; however, the combined use of antibiotics and vaccination in individual animals is not recommended. Because the vaccine is a live attenuated strain, concurrent use with antibiotics may lessen effectiveness of the vaccine. Combined vaccination and prophylactic antimicrobial treatment should be undertaken only after consultation with local veterinary public health or regulatory officials. Vaccination of neighboring herds should be initiated to prevent new infections resulting from either exposure to similar predisposing environmental conditions or through spread from initial outbreak sources. Controlling insects and both avian and mammalian scavengers will aid in preventing dissemination to neighboring premises.[501]

Vaccination is the major prophylactic measure undertaken to protect animals in endemic areas. Vaccination should be performed annually 4 weeks prior to turning animals onto pastures where outbreaks have occurred. A single dose of vaccine is given subcutaneously in the neck. In heavily contaminated areas, a second dose may be given 2 to 3 weeks later to afford better protection. The vaccine manufacturer's recommendations or local regulatory official's instructions should be followed regarding postvaccination market-withholding time for meat and discard time for milk. A minimum 42-day, postvaccination withholding period before slaughter is recommended. Localized swelling may occur at the site of vaccination. Goats and llamas may exhibit serious adverse reactions to the vaccine.

Ensuring that pastures are of good quality so that animals will not graze close to the soil will minimize exposure to spores. Avoiding rough feed that might traumatize mucosal surfaces will also decrease incidence rates. If possible, grazing animals on highly contaminated pastures should be avoided altogether and alternate uses encouraged for the land.

* Anthrax spore vaccine, Colorado Serum Co., Denver, Colo.

37.38.9 Public Health

Anthrax is a zoonotic disease. Humans develop three forms of anthrax: cutaneous, inhalational, and gastrointestinal.[497] Occurrence of the different forms depends on the route of exposure. Naturally acquired anthrax cases in humans in the United States are rare. When they occur, the cutaneous form is most common. Veterinarians are included among at-risk individuals because of the potential for contact with organisms while

handling infected carcasses. If anthrax is suspected, proper personal protective equipment, including physical barriers (e.g., gloves) and respiratory protection, should be used when collecting diagnostic samples and during carcass disposal. Naturally acquired inhalational anthrax in humans is rare because of the relatively high median lethal dose (LD_{50}, 8000 to 10,000 spores) required for infection and because spores carry static charges. These charges result in spores binding to larger particles, making aerosolization of spores more difficult.[500]

Concern about biologic weapons and terrorism has focused the public health community's attention on *B. anthracis* because it is an agent well suited for such use. Dissemination of a powdered form of anthrax spores through the mail in a bioterror attack on the eastern coast of the United States in 2001 demonstrated the effectiveness of *B. anthracis* as a biologic weapon. In that incident, both cutaneous and inhalational anthrax cases in people occurred.[505] *B. anthracis* is now classified as a "select agent," meaning that possession of virulent strains is federally restricted. Any isolation of *B. anthracis*, even from naturally occurring cases, must be reported to appropriate federal regulatory agencies (USDA) and any *B. anthracis* isolates securely stored or destroyed.[506]

1182

1183

37.39 LYME DISEASE

MONICA ALEMAN

JOHN E. MADIGAN

Lyme disease, also known as *borreliosis,* is one of the most important arthropod-borne bacterial infections in the United States. The disease is caused by the spirochete *Borrelia burgdorferi* and affects humans, horses, dogs, and cats.[507–510] Lyme borreliosis was first identified as a causative agent of an epidemic of juvenile inflammatory arthritis in children and adults in Old Lyme, Lyme, and East Haddam, Connecticut.[511,512] Therefore, medical references usually cite "Lyme disease" when referring to infection with *B. burgdorferi*.

37.39.1 Epizootiology

B. burgdorferi is widely distributed in the Northern Hemisphere. Prevalence of infection or exposure in horses has been reported to be high in the northeastern United States (50%), Midwest, Texas, and California.[513] Lyme borreliosis has been reported extensively in Europe, England, Russia, China, Japan, Southeast Asia, and South Africa.[514] *B. burgdorferi* is transmitted from ticks to humans and animals by ticks belonging to the *Ixodes ricinus* complex.[515] These ticks each feed three times, during the larval, nymphal, and adult stages.[511] The larvae and nymphs feed on wild animals, and adults are found most often on deer.[515] On the East Coast, *Ixodes scapularis* ticks are the principal vector, whereas on the West Coast, *Ixodes pacificus,* the western black-legged tick, is the main vector identified.[516] *I. scapularis* is seen from the Atlantic coast to Oklahoma and Texas.[517] A much higher percentage of *I. scapularis* ticks (12% to 99%) will carry the spirochete compared with *I. pacificus,* in which the maximum number of infected ticks is 4% to 5%.[516,517] *I. scapularis* larval ticks acquire the spirochete principally from *Peromyscus leucopus,* the white-footed mouse, and the nymphal stages are the major transmitters of disease to animals and humans.[518] With *I. pacificus* the California kangaroo rat, *Dipodomys californicus,* and the dusky-footed wood rat, *Neotoma fuscipes,* are the likely enzootic reservoirs of *B. burgdorferi*.[519]

Borrelia burgdorferi is found in many arthropods, but the major route of transmission to animals and humans is believed to be limited to the *Ixodes* species ticks. Experimental studies have demonstrated that ticks may harbor and transmit several pathogens, including the human granulocytic ehrlicheal agent and *B. burgdorferi,* at the same time.[520] Exposure to ticks infected with *B. burgdorferi* produced seroconversion without detectable histopathologic changes except for skin lesions in experimental horses.[521]*B. burgdorferi* is maintained in a 2-year enzootic cycle that involves *Ixodes* species ticks and mammals. Ticks are usually attached for at least 24 hours for *B. burgdorferi* transmission.[521] Birds are frequently infected with *B. burgdorferi* and may be responsible for the spread of the disease to new areas.[515]

37.39.2 Public Health Considerations

Surveillance for Lyme disease was initiated by the U.S. Centers for Disease Control and Prevention (CDC) in 1982, and in January 1991 it became nationally reportable. Cases have been reported from 46 states, and the annual number of Lyme disease cases has increased 18-fold, from 497 to 8803. It is now the most common tick-transmitted disease in the United States.

Borrelia burgdorferi organisms have been recovered from the urine of feral white-footed mice, *Peromyscus leucopus*.[522] Contact transmission has been reported among white-footed mice,[522] further complicating the understanding of transmission. Because of lack of any proof to the contrary, it is generally believed at this time that any potential increased risk to humans from infected animals is attributable to animals bringing ticks into areas of human habitation rather than any animal transmission.[523]

37.39.3 Molecular Biology

Immunochemical analysis of North American strains of *B. burgdorferi* reveal two abundant surface proteins, termed outer surface protein A (OspA, 30 to 32 kD) and outer surface protein B (OspB, 34 to 36 kD).[524] The 41-kD antigen is located on the flagellum and is similar to the flagellar antigens of other spirochetes.[525] All isolates to date have four to nine pieces of extrachromosomal plasmid DNA. Plasmid may code for proteins that are important in pathogenicity because the loss of infectivity of isolates that have been heavily passaged in the laboratory correlates with the loss of particular plasmid in culture.[526] Recent work suggests that *B. burgdorferi* can vary its antigenicity similar to the relapsing fever—causing *Borrelia* (e.g., *B. hermsii)*, although by a different mechanism and by using subtle alterations in the genome.[527]

37.39.4 Clinical Signs

37.39.4.1 EQUIDS

Clinical signs are not specific but may include low-grade fever, stiffness, lameness in more than one limb, muscle tenderness, hyperesthesia, swollen joints, and behavioral changes.[528,529] The most common signs are lameness and hyperesthesia. These signs have been reported more often in performance horses. *Borrelia* may be found concurrently with *Anaplasma phagocytophila* in *Ixodes* ticks, resulting in dual infection in the horse.[520]

Horses from endemic areas have serologic evidence of exposure.[530–533] Attempts have been made to correlate individual cases of arthritis, uveitis, or brain infection with this organism.[532,534,535] Experimental infection has produced seroconversion and shedding of the organism in the urine and seroconversion in contact controls.[536] In the United Kingdom, most seropositive horses do not show clinical signs of disease.[537]

37.39.4.2 RUMINANTS

Although there are some reports in the literature of seropositive animals with arthritis, the evaluation performed on the patients makes it difficult to determine if *B. burgdorferi* was the cause of the signs.[538] It appears at this time that many ruminants are seropositive to *B. burgdorferi* but do not have clinical signs. Whether these tests lack specificity in the ruminant or represent a host-adapted strain of the *Borrelia* organism is unknown.[539] A recent report correlates exposure of *I. scapularis* ticks in dairy cattle with titers to *B. burgdorferi*.[540] An attempt to develop a more specific test in cattle using the 41-kD flagellin antigen has recently been reported.[541]

37.39.5 Diagnosis

A number of diagnostic methods are available, including IFA, ELISA, indirect CF, and Western blot.[535,538] Culture of the organism requires special media (BSK) and is difficult but may be possible from blood, urine, or CSF. Diagnosis of recent or active *Borrelia* infection has been based on high ELISA titers (>300 units kinetics-ELISA [KELA]), positive Western blot, or PCR.[542] In an experimental infection study, *I. scapularis* ticks infected with *B. burgdorferi* were placed in healthy ponies for 7 days. These ponies developed detectable antibody at 5 to 6 weeks.[542] KELA units were elevated at 3 to 4 months postexposure and remained elevated for several months until euthanasia. Western blot became positive at 10 to 12 weeks postexposure.[542] Throughout the study the organism was isolated from the skin where infected ticks were attached. Histopathologic examination revealed lymphohistiocytic nodules in the dermis, lymph node enlargement, and perivascular and perineural lymphocytic infiltrates in the skin, fascia, and perisynovial membranes. PCR was useful for the detection of organisms in the skin, lymph nodes, skeletal muscle, fascia, and synovial membranes. Less often, the organisms were detected in heart, pericardium, kidney, bladder, and meninges.[542] More recently, detection of serum antibodies to *B. burgdorferi* in horses was improved (84% detection) by using an ELISA based on whole-cell and recombinant antigens.[543]

1183 1184

37.39.6 Treatment

Antibiotic susceptibility of *B. burgdorferi* has been reported but may lack appropriate standardization.[544] *B. burgdorferi* is sensitive to tetracycline and moderately sensitive to penicillin. Amoxicillin, ceftriaxone, and imipenem are highly active against *B. burgdorferi*. Aminoglycosides, ciprofloxacin, and rifampin lack activity.[545] Doxycycline twice daily in humans has been frequently used. Probenecid and ampicillin or amoxicillin also have been used.[544] When CNS involvement is present, ceftriaxone or IV penicillin G has been used. The appropriate duration of therapy is unknown but is related to the stage of infection.

Three different antimicrobials—ceftiofur sodium (2.2 mg/kg/day IM), doxycycline (10 mg/kg/day PO), and tetracycline (5 mg/kg/day IV)—were used for a 28-day period in experimentally infected ponies.[546] High KELA titers and *B. burgdorferi* isolation from skin biopsies confirmed infection. Antimicrobial therapy was initiated 3 months postexposure. Tetracycline was the most effective antimicrobial; it decreased KELA antibody titers (<110 units) during and months after treatment, and bacterial isolation became negative in tissues. However, tissues were still positive for the spirochete on PCR.[546] The efficacy of decreasing titers of tetracycline in the clinical setting has not been highly successful.[547] Proposed treatment for *Borrelia* infection includes tetracycline (6.6 mg/kg IV every 12 hours), doxycycline (10 mg/kg PO every 12 hours), or ceftiofur (2.2 mg/kg IM every 12 hours) for 3 to 4 weeks.[542]

A recombinant outer surface protein A (rOspA) subunit vaccine was shown to be effective in preventing infection in challenged horses with infected ticks.[520,548] Specific recommendations for its use in the clinical setting are lacking.

37.40 TULAREMIA

BRADFORD P. SMITH

Tularemia is an infectious disease of humans, wild animals, livestock, and pets caused by *Francisella (Pasteurella) tularensis*. The organism is a facultative, intracellular, non-spore-forming, gram-negative coccobacillus that survives frozen or in mud and water for long periods (>1 year),[549] but it only survives for hours in carcasses. The natural hosts are rabbits and rodents, and transmission to livestock occurs chiefly through ticks, fleas, deerflies, and other insects.[550] Sheep are the most frequently affected livestock species. Massive epidemics with a high mortality in range sheep have been reported.[550] Humans are stricken with a plaguelike illness when bitten by infected ticks, fleas, or insects and from handling infected rabbits or other infected animal carcasses.[551] Sheep shearers may become infected by bites of parasites from the sheep. Disease in horses has also been documented.[552] Oral infection from contaminated water occurs, so fresh water should be provided.[550]

The disease causes an acute septicemia, with localization and granulomatous lesions in the organs (particularly the liver and spleen). Signs are very nonspecific, as expected with bacteremia, and include fever, anorexia, lethargy, and in some cases cough, rapid respiration, or diarrhea. Stiffness and edema of the limbs may be seen. The course of disease is usually 2 to 14 days.

Agglutination titers in recovered affected sheep range from 40 to 5000. Agglutination titers persist for very short periods (21 days) in horses,[550] probably because they measure mainly IgM. Diagnosis is based on culture of the organism from blood or organs. Diagnosis can also be made by IFA testing or PCR.[553]

Necropsy usually reveals ticks on the carcass. Often, reddened or necrotic areas appear in and under the skin at the site of infected bites. Regional lymph nodes may be swollen and congested. Congestion and edema of the lungs are common. Differentials include other bacteremias such as *Mannheimia (Pasteurella) haemolytica* in sheep, *Histophilus somni (Haemophilus somnus),* in cattle, *Mycoplasma mycoides* subspecies *mycoides* in goats, and anthrax in all livestock. Treatment early in the course of infection is effective. Aminoglycosides, tetracyclines, or cephalosporins all are probably beneficial initially, until results of antimicrobial susceptibility testing are available. Insecticide removal of ticks from affected animals and herdmates is important. No vaccine is currently

available, so insect and tick control in endemic areas remains the major prevention. Because oral infection from contaminated water has also been documented, fresh water should be provided.

37.41 *CORYNEBACTERIUM PSEUDOTUBERCULOSIS* INFECTION

MONICA ALEMAN

SHARON J. SPIER

37.41.1 Definition

Corynebacterium pseudotuberculosis infections occur worldwide and cause external and internal caseous lymphadenitis in sheep and goats; cutaneous excoriated granulomas and mastitic, visceral, or mixed infection in cattle; and ulcerative lymphangitis and external and internal abscesses in horses.[554–557] Subacute to chronic lymphadenitis and pneumonia have been reported in humans handling infected sheep.[558,559] Several zebras in the United States developed severe or multiple internal abscesses and died weeks after being exposed to horses in California.[560] There have been reports of the disease in camels, alpacas, and buffalo.[561–563]

37.41.2 Microbiology

C. pseudotuberculosis infection is caused by a 2-µm, gram—positive, intracellular, nonmotile, pleomorphic rod-shaped, facultative anaerobe.[554,564] *C. pseudotuberculosis* grows well at 37° C on blood agar in 24 to 48 hours, and it forms small, pinpoint-diameter, whitish, opaque colonies that are surrounded by a weak zone of hemolysis. Because of the high content of lipids in the bacterial cell wall, particularly corynomycolic acid, the colonies spatter in a flame can be pushed across the agar surface.[554] The high content of lipids may facilitate survival of the organism in macrophages.[565] Two species-specific biotypes of *C. pseudotuberculosis* have been identified based on differences in nitrate reduction[559] and DNA fingerprinting techniques.[566–568] Strains isolated from small ruminants are nitrate negative, strains from horses are nitrate positive (except for two horses that were nitrate negative), and both strains have been isolated from cattle.[555,559,567,569] From DNA studies the terms “biovar equi” for nitrate-positive and “biovar ovis” for the nitrate-negative strains were proposed.[566] Recent studies revealed that there is more heterogeneity of the isolates of *C. pseudotuberculosis* from small ruminants and from horses[567,568,570] and concluded that nitrate reduction may not absolutely distinguish between the isolates as does ribotyping.[567] On the basis of ribotyping, sheep and goats have specific isolates throughout the world, and horses and cattle have two distinct groups of isolates depending on geographic location, with one from the United States and the other from South Africa and Kenya.[567] Natural cross-species transmission does not seem to occur.[554]

1184

1185

Corynebacterium pseudotuberculosis produces various exotoxins, including phospholipase D (PLD), sphingomyelinase, inhibitory factor of staphylococcal beta hemolysin, hemolysis factor, dermanecrotoxins, and mouse lethality toxins.[571] PLD and sphingomyelinase are important in the pathogenesis of the disease because they hydrolyze lysophosphatidylcholine and sphingomyelin, respectively, thus degrading the endothelial cell wall and increasing vascular permeability.[572] The synergistic activity of sphingomyelinase with the exotoxin of *Rhodococcus equi* in lysing RBCs in agar forms the basis for the synergistic hemolysis inhibition (SHI) test.[573]

Most recently, molecular characterization of *C. pseudotuberculosis* isolates from four different states (California, Colorado, Kentucky, and Utah) was determined by random-amplified polymorphic DNA (RAPD) PCR.[574] The identity of *C. pseudotuberculosis* in these isolates was confirmed by the presence of the gene encoding the PLD toxin by PCR. Ten distinct genotypes (I to X) were identified. Types IV to VIII and X were isolated only from horses, whereas types III and IX were isolated from horses and cattle. This study also found differences in genotypes among states as follows: California (III, IV, V, VI, IX, X), Colorado (III, VI, VII, IX, X), Kentucky (III, IV, V, VI, VIII), and Utah (III). In horses, types III, VI, and X were isolated from internal abscesses from California and Kentucky, and types III to VI and VIII to X were isolated from external abscesses from one or more states.[574]

37.41.3 Clinical Signs and Differential Diagnosis

37.41.3.1 SHEEP AND GOATS

C. pseudotuberculosis causes caseous lymphadenitis (CLA) in sheep and goats worldwide. CLA is a major cause of poor production, premature culling, and mortality. The two forms of CLA are external and internal abscesses.[575] The infection in small ruminants is primarily characterized by suppuration and necrosis of the large, superficial lymph nodes. *External abscesses* are found more often involving the mandibular, parotid, prefemoral, or prescapular lymph nodes. The exudate present in those abscesses is thick or inspissated and may appear white in sheep and greenish in goats.[554] A breed association with the type of CLA cutaneous lesions was observed in an outbreak in a commercial ram stud in Scotland.[576] The disease is commonly known as “cheesy gland” in Australia. Differential diagnosis should include abscesses caused by other organisms, trauma, seroma, hematoma, foreign body, injection reaction, and less frequently, tumors. Because *C. pseudotuberculosis* infection represents a major herd health problem, culturing of the abscess to determine the causative agent is important. Mastitis occasionally develops.[556]

Internal abscesses can be found in the lungs, kidneys, and mediastinal, bronchial, mesenteric, and lumbar lymph nodes.[575] Chronic weight loss is the most common presenting complaint. Other clinical signs are related to the organ or tissues affected. Other diagnostic procedures may be necessary for the differentiation of internal abscesses as the cause of weight loss. Signs of spinal cord compression by vertebral abscesses have been seen in lambs born in unsanitary conditions.[554] Knowledge of the local prevalence can help in the diagnosis of the infection when uncommon anatomic locations are affected. The prevalence in large breeding operations in endemic areas is estimated at 5% to 10%.

37.41.3.2 CATTLE

The infection in cattle occurs as a herd problem with a sporadic incidence. The most common clinical form affecting cattle is cutaneous excoriated granuloma; other forms include mastitis and visceral and mixed infections.[556] In the most common form the lesions do not occur as abscesses; instead, they appear as ulcerative, exuding granulomatous lesions as large as 20 cm in diameter with necrotic areas that are easily removed surgically, leaving granulation tissue underneath.[554,557] The location of the lesions is usually in the lateral exposed areas of the body: face, neck, thorax, and flanks. The exudate varies from bloody to thick and greenish in color. The lesions heal spontaneously in 2 to 4 weeks and do not appear to cause significant illness or decrease milk production in cattle, as reported in California.[554] However, monthly milk production

was decreased by 6% in Israeli cattle.[557] Prevalence of the infection has been reported as high as 10% in California dairies.[554] Morbidity was reported as high as 35% in Israeli herds.[557] Management problems, such as broken posts or exposed wires, traumatize the skin of cattle, allowing penetration of the organism. Young cattle appeared to be less susceptible to the disease than older cattle in Israel.[557] The differential diagnoses include trauma, foreign body, and other masses (e.g., tumors). Cutaneous lesions and mastitis were seen in 6% and cutaneous lesions with concurrent visceral involvement in 1.6% of the Israeli cases.[557] The rest of the cows (92%) only had the cutaneous form.[557] The most affected organ in the visceral form was the lung.[557] The infection has been reported in bison from Egypt, resulting in severe emaciation and edema in the ventral areas and flanks.[561]

37.41.3.3 CAMELS AND CAMELIDS

Caseous lymphadenitis has been reported in alpacas in South America.[577] A recent study documented five young alpacas (22 days to 14 months old) in North America with CLA or subcutaneous abscesses that developed during late summer and early fall.[563] The alpacas did not appear clinically ill but developed swellings that progressed to abscesses. The abscesses (1 to 3 per alpaca) were located in the submandibular and cervical areas and in one case adjacent to the eye. Abscess excision appeared to be the most effective treatment in those cases. Differential diagnoses include abscesses caused by *Streptococcus* species, *Corynebacterium* species, and *A. pyogenes*.[578] Severe lymphadenitis was reported in camels in Asia.[562] A study on experimental infection of adult alpacas resulted in abscesses at the inoculation site and renal lymph nodes.[579]

37.41.3.4 HORSES

Three forms have been described in horses: ulcerative lymphangitis, external abscesses, and internal abscesses. In a study of *C. pseudotuberculosis* infection in horses from California, ulcerative lymphangitis was diagnosed in 1%, external abscesses in 91%, and internal abscesses in 8% of the cases.[580] There appears to be no breed or gender predilection for development of the infection. Ulcerative lymphangitis appears as a severe cellulitis, in which the lymphatics are affected in one or more limbs, with multiple draining ulcerative lesions. Horses often develop a non-weight-bearing lameness, fever, lethargy, and anorexia. This form of the disease has a worldwide distribution and often becomes chronic, resulting in limb edema, lameness, weakness, and weight loss.[554] The differential diagnosis should include blunt trauma, fracture, foreign body, puncture wounds, nonseptic cellulitis, staphylococcal cellulitis, and other septic cellulitis.

1185

1186

The median age for horses with external abscesses is 5 years (range, 3 months to 28 years).[580] Young horses appear to be predisposed to infection because 52% of the cases in a large retrospective study were 5 years or younger.[580] Only a low number of cases involved foals under 6 months of age, suggesting that foals born to mares in endemic areas may be protected for several months by colostral antibodies.[580] The external abscesses located primarily in the pectoral and ventral abdominal regions are common in geographically restricted areas of the western United States (Texas, New Mexico, Nevada, California) and Brazil.[554,555,580,581] However, the infection has been diagnosed in other states, such as Arizona, Colorado, Kentucky, Utah, and Wyoming.[574,582] This form of infection is commonly known as “pigeon fever” because of the large size of the pectoral abscesses with the appearance of a pigeon's breast. “Dryland distemper” is another name given in relation to its geographic distribution primarily in the arid areas. Other common

anatomic locations are the prepuce, mammary gland, axilla, inguinal region, limbs, and head. Abscesses involving the head include the ears, eyelids, forehead, and maxillary and mandibular regions.[580] Severe facial suppurative cellulitis and panniculitis with skin sloughing has also been reported.[583] Other, less common areas are the thorax, neck, parotid gland, guttural pouches, larynx, flanks, umbilicus, tail, and rectum. Septic joints and osteomyelitis have been reported.[580]

A large area of edema develops in the area of abscess formation. As the abscess matures, the area becomes hard and painful, and some become very large, particularly in the pectoral area. The abscesses typically have a thick capsule, measuring up to 10 cm, and can cause severe lameness if located in the axillary or inguinal region.[555,580] Maturation can be slow and drainage difficult to establish if the abscess lies deep to muscle. Once drainage is established by spontaneous rupture or lancing, the majority of the cases resolve within 10 to 14 days without complications. The abscesses may contain 5 to 400 mL of thick, tan, purulent exudate.[555] The majority of the horses present with a single abscess rather than multiple abscesses.[580] About 25% of animals develop fever up to 40° C (104° F). Other signs are nonhealing wounds, lameness, ventral dermatitis, and less often, depression, anorexia, mastitis, and other signs, depending on the abscess location.[580]

The vast majority of horses (91.4%) had complete recovery, with no recurrence of infection in subsequent years, implying a long-lasting immunity. However, 8.6% of the infections persisted for more than 1 year or had recurrence as external or internal abscesses.[580] In sheep and goats, humoral and cellular immune responses develop after infection, and macrophages acquire the ability to kill the organism.[558] The case fatality for horses with external abscesses is very low (0.8%).[580] The differential diagnosis for external abscess, particularly pectoral, should include trauma, seroma, hematoma, foreign body, and abscess caused by a different organism.

In a large retrospective study of *C. pseudotuberculosis* infection in the horse, 8% of 538 horses developed internal abscesses.[580] In two different studies, almost half to 63% of horses that had internal abscesses also had concurrent or a history of external abscesses.[580,584] In a study of 30 horses with internal abscesses, a female predilection (70%) was apparent.[584] The mean age is 8 years (range, 10 months to 23 years).[580,584] The most common clinical signs are anorexia, lethargy, fever (up to 41.1° C), tachycardia, and weight loss. Other signs are colic, pale mucous membranes, ventral/limb edema, ventral dermatitis, ataxia, hematuria, nasal discharge, and abortion.[580] The most frequently affected anatomic location is the liver, followed by mesentery, mediastinum, lungs, kidneys, diaphragm, spleen, pericardium, blood, and uterus.[575,584,585] A postmortem examination on an aborted fetus from a mare with pneumonia revealed *C. pseudotuberculosis* abscesses in the liver, lungs, spleen, diaphragm, kidney, and bladder.[584] Bacteremia may also occur. Both single-organ and multiple-organ involvement have been documented.[584] The case fatality for horses with internal abscesses ranges from 30% to 40%.[580,584] The differential diagnosis should include other types of abscesses, such as those caused by *Streptococcus, Actinomyces, Staphylococcus, Rhodococcus equi* in foals, *Coccidioides immitis,* and anaerobes, as well as neoplasia and other causes of weight loss. The clinical signs and differential diagnosis will depend on the location of the abscess.

37.41.3.5 HUMANS

Human infection may result from the consumption of unpasteurized infected milk or milk products, continued close contact with infected animals, handling contaminated equipment, and exposure of wounds

with exudates.[558,586] Human infection has been reported from strains of small ruminants.[558] Transmission from horses to humans has not been reported, but precautions when handling infected horses should be taken. Infection in humans occurs as a subacute to chronic lymphadenitis and pneumonia.[558]

37.41.4 Clinical Pathology and Laboratory Diagnosis

Almost half the horses with external and/or internal abscesses had anemia of chronic disease in one study.[580] Leukocytosis with neutrophilia and elevated fibrinogen are common features of developing bacterial infections, particularly in the case of internal abscesses.[580] Leukocytosis with neutrophilia was seen in 36% and 76% of the horses with external and internal abscesses, respectively.[580] Hyperproteinemia caused by increased globulins was observed in 38% and 59% of the horses with external and internal abscesses, respectively.[580] Similarly, infected cattle and small ruminants had increases in WBC counts.[557,576]

Peritoneal fluid from 93% of the horses with abdominal abscesses was abnormal.[580] The remaining horses with abdominal abscesses and normal peritoneal fluid had abscesses located retroperitoneally in the kidneys without involvement of other abdominal structures. *C. pseudotuberculosis* was isolated in 32% of the samples of peritoneal fluid.[580] Failure to isolate the organism from peritoneal fluid does not rule out the disease. The organisms could be located retroperitoneally, or sequestered within a thick capsule, or suppressed by local factors or nucleated cells.[587]

The ELISA test for the detection of cell wall antigens is reportedly not very accurate in horses.[554,571] ELISA appears to be more useful for detection of infection in sheep.[588–591]

Another useful diagnostic aid is the synergistic hemolysis inhibition (SHI) test, which measures IgG response to the exotoxin in the patient's serum by detecting the highest dilution that will prevent hemolysis of *R. equi* exotoxin—sensitized bovine RBCs when mixed with *C. pseudotuberculosis* exotoxin of a known concentration.[573,592] The IgG response to the exotoxin depends on the chronicity and severity of the infection and antibody availability.[554] It has been reported that a serum antibody titer of 1:128 indicates exposure, whereas 1:512 or higher indicates the presence of infection.[554] Studies in goats have demonstrated that most animals have serum antibody titers that correlate with bacterial culture results.[593] The SHI test can be used in sheep and goats to monitor prevalence and exposure of incoming animals and to detect subclinical infections.[554,592] Only 40% of horses with external abscesses, in which the infection was confirmed by culture, had serum antibody titers of 256 or higher. However, a low SHI titer does not rule out the disease. Possible reasons for lack of titers include (1) acute onset of infection and rapid maturation of the abscess before developing an immunoglobulin response, (2) presence of a thick capsule isolating the organisms and preventing a serologic response, and (3) consumption of antibody during active infection.[554,580] Many horses that are seronegative at drainage of an external abscess seroconvert at a later time. In contrast, almost all horses with confirmed *C. pseudotuberculosis* internal abscesses have SHI titers of 512 or higher.[575,584] The high titers in horses with internal abscesses probably reflect the chronicity of the disease and the resulting prolonged immune stimulation. Prolonged seropositivity has been observed in horses and goats.[580,592,594] The SHI test appears to be a reliable ancillary aid for the diagnosis of internal abscesses in horses.[580,584] Presence of a SHI titer greater than 512 can occasionally be found in horses with external abscesses and exposed herdmates.

Other serodiagnostic tests used in sheep and goats are tube agglutination, complement fixation, and gel immuno-diffusion.[571,595]

A presumptive diagnosis can be made based on the history, local prevalence, time of the year, clinical signs, and characteristics of the exudate.[554] For the diagnosis of internal abscesses, the previous features must be considered, in addition to the presence of an inflammatory leukogram with elevated fibrinogen, serum chemistry abnormalities, abnormal peritoneal fluid or transtracheal wash, positive blood culture, SHI titer of 512 or higher, and ultrasonographic or radiographic evidence of masses.[580,584] The definitive diagnosis is established through the isolation of the organism from abscesses or draining wounds. The organism is readily isolated and grows well in blood agar in 24 to 48 hours, even when contaminant bacteria are present.[580]

37.41.5 Pathophysiology and Epidemiology

C. pseudotuberculosis is a soil-borne organism that survives for months to years, even in direct sunlight at environmental temperatures.[558,596,597] The incidence of infection in horses varies considerably from year to year. External and internal abscesses in horses can present at any time of the year but are seen more often during the fall and early-winter months, with the highest incidence in September, October, and November.[580] However, internal infections are more frequently seen in November through January, 1 to 2 months after the peak number of cases with external abscesses.[584] The largest numbers of equine cases have been observed during the dry months of the year, after heavy rainfall, which may result in optimal breeding conditions for insects.[555,580,581] The seasonal incidence in horses has been associated with the presence of biting insects such as *Haematobia irritans* (horn fly), which causes ventral midline dermatitis from its feeding pattern. Insect vectors involved in the transmission of disease in horses, such as *H. irritans, Stomoxys calcitrans,* and *Musca domestica,* were identified by detecting the PLD exotoxin gene of *C. pseudotuberculosis* in an endemic area.[598] The results of one study suggest that the disease could be transmitted through horse-to-horse contact, vectors, or contaminated soil.[599] Temporal and spatial analysis indicated an incubation period of 3 to 4 weeks in horses. There is no breed or gender predilection[580]; however, a retrospective study indicated a predilection for internal abscesses in females.[584] A case-control study in an endemic area revealed that young adult horses less than 5 years of age had increased risk of infection.[600] Horses housed outside or with access to an outside paddock, or in contact with other horses on pasture, appeared to be at higher risk than stabled horses.[600]

The disease in cattle from Israel occurred during the spring and summer dry season, from March to October, when the housefly population is high.[557] *C. pseudotuberculosis* was isolated from houseflies collected over an Israeli cow lesion.[601] The infection in cattle may spread by direct contact or indirectly by houseflies or fomites.[557] The disease in sheep and goats is not seasonal, and transmission is through contact of exudate from a draining abscess from animal to animal or through contaminated equipment.[555] Lambs born in contaminated surroundings can be infected through the umbilicus, mouth, or inhalation.[554] Sheep that acquire the organism orally or from shearing wounds tend to have parotid, submandibular, prefemoral, or thoracic abscesses.[554] Goats can be infected when wounds are exposed to contaminated milking equipment. The incubation period is long and variable. In experimental infections in small ruminants, the incubation period was 2 weeks to several months.

The pathogenesis of the disease in horses is not clear, but it has been speculated that the organism enters the equine host through skin or mucous membrane abrasions or wounds, as confirmed in sheep.[602,603] Experimentally induced infections in small ruminants revealed that once *C. pseudotuberculosis* gains access through wounds or abrasions, the organisms spread to the subcutaneous or submucosal lymphatics, where they are phagocytosed by macrophages that migrate to the invasion site to engulf the organism.[604] The organism survives intracellularly because of its high content of lipids (e.g., corynomycolic acid), which resist the action of lysosomal enzymes.[564,604] *C. pseudotuberculosis* replicates in the phagolysosome; if large numbers of organisms are engulfed, phagocytic cells die. Experimental inoculation of the organism in sheep revealed a massive infiltration with polymorphonuclear neutrophil leukocytes (PMNs),[605] which are believed to carry the bacteria to regional lymph nodes.[554] A PLD toxin of approximately 31.5 kD, produced by all *C. pseudotuberculosis* isolates, increases the vascular permeability, causing spread of the organism regionally and systemically.[558,593,606] Development of abscesses at secondary locations in horses can occur in up to 25% of the cases.[580] PLD toxin can cause necrosis and thrombosis of the lymphatics and may enhance survival and multiplication of the organism through complement depletion and inhibitory effects on phagocytic cells.[558] The corynomycolic acid and PLD toxin contribute to the inflammation, edema, and pain during abscess development.[607] The profound reaction of these compounds is probably responsible for the thick abscess capsule that develops as phagocytes accumulate in the abscess core. The abscess eventually matures and drains, but if removal of infected material is incomplete, recurrence may be expected, particularly in small ruminants.[554] The development of internal abscesses in horses is unclear but has been postulated to result from hematogenous or lymphatic spread of bacteria from more superficial sites.[554,580,584]

37.41.6 Treatment and Prognosis

Important considerations when treating external abscesses are (1) to allow for the abscess to mature; (2) to establish drainage, then collect and dispose of the infective exudate; and (3) to lavage the wound with an antiseptic solution. In a retrospective study in horses, most external abscesses were incised to establish drainage, and some animals received antimicrobials after drainage in an effort to decrease cellulitis. Many horses received no treatment, and the abscesses broke and drained on its own. Other horses were treated only with antimicrobials. The outcome was successful for 99% of the horses with external abscesses.[580] Horses with abscesses in the axillary region or deep within muscles have considerable pain, necessitating incision and drainage. Ultrasound is useful for the detection of the location of deep abscesses.[584]

1187

1188

In one report the median resolution time for horses with external abscesses that did not receive antimicrobial therapy before abscess drainage was 18 days, versus 30 days for the horses that received antimicrobials.[580] These data suggest that systemic antimicrobial therapy before abscess drainage in horses with external abscesses may prolong the course of the disease.[580] However, when abscesses recur, drainage and concurrent antimicrobials may improve the chance of resolution. Conversely, long-term (minimum 4 to 6 weeks) antimicrobial therapy is necessary for the treatment of internal abscesses and ulcerative lymphangitis. The median resolution time for horses with internal abscesses treated with antimicrobials was 36 to 42 days, with a maximum duration of 97 days.[580,584] The case fatality for horses with internal abscesses treated with antimicrobials was 30% to 40%, but 100% if not treated.[580,584] In vitro, *C. pseudotuberculosis* is susceptible to almost all common antimicrobials, including penicillin, trimethoprim-sulfonamide, tetracycline, cephalosporin, chloramphenicol, erythromycin, and rifampin.[608,609] Most isolates are resistant to nitrofurans, cycloheximide,

and nalidixic acid.[609] Bacitracin has marked activity against the bacterium.[610] In selecting an antimicrobial, the clinician must consider (1) the intracellular location of the organism, (2) presence of a thick abscess capsule and presence of pus, (3) lengthy course of treatment that may be required, (4) risk of complications (e.g., diarrhea), and (5) cost. Antimicrobial-associated diarrhea was seen in 6% of horses receiving antimicrobials (rifampin, trimethoprim-sulfas, penicillin) for *C. pseudotuberculosis* infection in a retrospective study.[580] Additional therapies include marsupialization of internal abscesses if location allows. NSAIDs such as phenylbutazone or flunixin meglumine may be used to control the pain and fever while waiting for external abscesses maturation.

The prognosis for external abscesses is good. Most resolve in 3 weeks from the day of drainage.[554] The prognosis for horses with internal abscesses and ulcerative lymphangitis is guarded. The prognosis improves if infection is detected early and appropriate therapy administered.

In a bovine study the skin lesions on individual cows healed on average in 23 days after local or parenteral treatment; 17% of severely affected cattle were culled.[557] Simple drainage in small ruminants does not usually result in resolution of the disease and creates potential sources of infection. Dilute iodine solutions can be used for abscess lavage. Complete excision of the abscess under general anesthesia may be necessary to keep the abscess from draining and to prevent the spread of infection to other animals.[554] The treatment of choice in small ruminants is surgical removal of the affected lymph nodes.

37.41.7 Prevention and Control

Even though *C. pseudotuberculosis* infection is one of the most frequently diagnosed infectious diseases in California, little is known about its prevention and control. General recommendations to prevent the spread of the infection are isolation of infected animals, fly control, good sanitation, careful shearing practices, disinfection of contaminated fomites, and careful disposal of bedding. In small ruminant farms the morbidity can reach 100%, with depopulation being the most economic option. Because of the ability of the organism to survive in soil and fomites, the potential for environmental contamination is very high.[596,600]

Immunization trials using whole cells, cell walls, toxoids, and bacterin-toxoid combinations have been performed in the prevention of CLA in small ruminants.[611–615] These vaccines have been shown to provide a high degree of protection, decreasing the number of infected sheep and the number of abscesses per sheep. *Corynebacterium pseudotuberculosis* toxoids are commercially available for sheep and goats.* The use of autogenous bacterin-toxoid in horses resulted in fewer abscesses and less postchallenge pain in experimentally inoculated horses, but did not reduce the incidence of infection in one farm because of a low prevalence of disease.[616] Use of an experimental bacterin-toxoid demonstrated increased SHI titers after two injections; however, the protection remains to be established.[617]

38 Chapter 38 Diseases of the Bones, Joints, and Connective Tissues

Consulting Editors

Robin M. Dabareiner

38.1 PHYSITIS (EPIPHYSITIS)

A. BERKLEY CHESEN

38.1.1 Definition and Etiology

Physitis is a term used to describe a developmental orthopedic condition in which there is a disturbance in endochondral ossification at the physis, or growth plate. Of the developmental orthopedic diseases—osteochondrosis, physitis, subchondral bone cysts, flexural limb deformities, cuboidal bone malformation, acquired angular limb deformities, and juvenile arthritis—physitis is the most common.[1,2] In one study of 1711 Irish thoroughbred foals, 67% had signs of developmental orthopedic disease.[2] The term *physitis* may better be defined as "physeal dysplasia" because typically there is no evidence of an inflammatory process.[3]

Physitis has been seen in growing cattle as a result of copper deficiency and interactions with molybdenum, zinc, and sulfates, as well as in calves raised on slatted floors.[4] Two common antagonists of copper include zinc, which at high levels prevents absorption of copper by the body, and molybdenum, which is found in alfalfa.[5] Other animals in which physitis has been reported include show rams being heavily fed and sheep and goats with pregnancy-associated ephiphysitis.[4]

Physitis typically affects the given physis during its active growth phases. Factors implicated as causing physitis in horses include the following[4]:

1 A genetic component for faster-growing horses and for specific conformation (e.g., upright and pigeon-toed appearance).

2 Overweight foals.

3 Growth spurts in foals.

4 Intake of high levels of carbohydrates, causing hormonal changes and affecting the physis.

5 Improper mineral balance (e.g., copper or zinc deficiency).

6 Excessive or deficient calcium intake.

7 Excessive exercise, especially on hard ground, may cause strain on maturing cartilage.

38.1.2 Clinical Signs

Physitis in horses is seen mainly in three specific locations at certain ages. Foals ranging in age from 3 to 6 months most often have signs of physitis at the distal metacarpal/metatarsal growth plate (with or without involvement of the proximal physis of the first phalanx). Older foals (8 to 24 months) may have signs of physitis at the physis of the distal radius.[6] Less frequently the distal physis of the tibia may be involved. Physitis is characterized by firm swellings that may be warm and painful on palpation. Typically the swellings are medial because of increased weight bearing on this portion of the limb.[6] Foals may or may not be lame. Radiographic changes include a sclerotic, roughened physis with an irregular metaphyseal shape.[2] If the physitis continues, the growth plate may close prematurely, leading to an irreversible angular limb deformity (usually a varus deformity because of decreased growth on medial physis).[6]

38.1.3 Diagnosis

A diagnosis of physitis is usually made by appreciation of the clinical signs, including warm, sometimes painful, firm swellings in the locations previously cited. Physitis at the fetlock may appear to have an hourglass appearance if the proximal physis of the first phalanx is affected. A convex appearance just proximal to the distal tibial and radial physis may be seen early in the disease process.[6] Recently, a quantitative method for detection of physitis was investigated in thoroughbred foals.[2] This method is based on the observation that when the physis is enlarged, both the metaphysis and the ephiphysis are more concave.[7] Results of this study show that epiphyseal concavity may indicate the degree of physeal swelling by using the maximum second derivative value of that contour. Radiographically, physitis is characterized by a growth plate that is irregularly thickened with sclerotic adjacent bone.[2]

38.1.4 Treatment and Prognosis

Treatment of physitis should begin with management changes. Special attention should be given to the nutrition of these foals and weanlings. Ensuring proper balance of minerals, especially calcium and phosphorus, as well as adequate amounts of trace minerals such as copper and zinc, is necessary. Copper is required for successful cross-linking of collagen. When a copper deficiency exists, the cartilage matrix weakens and microfractures occur. Because mare's milk is very low in copper, foals rely on hepatic stores gained during the last trimester of gestation.[5] One study showed that supplementation of mares with copper during gestation significantly reduced radiographic signs of physitis in their foals at 150 days of age. Supplementation of foals did not affect the incidence of physitis in the same study. Based on these results, supplementation of mares during the second half of gestation with copper on farms with a high incidence of physitis may be beneficial in preventing physitis in their foals.[8] A general reduction in energy is needed to slow growth rates and, when necessary, decrease body weight. Total concentrate for nursing foals should be 0.5 to 0.75 kg/100 kg body weight, 1 to 1.5 kg/100 kg for weanlings, and 0.5 to 1 kg/100 kg for yearlings.[4]

Varying degrees of discomfort are associated with physitis. For horses with very painful, warm physes, the judicious use of nonsteroidal antiinflammatory drugs (NSAIDs) is indicated. Exercise restriction, specifically stall rest, is indicated in affected horses. Without exercise restriction, these horses continue to load the physes, which may lead to permanent conformational changes, such as angular limb deformities.

With early detection and treatment, the prognosis for physitis is good for athleticism.

38.2 OSTEOCHONDROSIS

JASON C. MEZ

38.2.1 Definition and Etiology

Osteochondrosis is a developmental orthopedic disease characterized by failure of, or defect in, endochondral ossification that can lead to cartilage flaps, osteochondral fragments, or subchondral bone cysts. It is classified as a *developmental orthopedic disease* (DOD) along with physitis, angular limb deformities, subchondral bone cysts, flexural deformities, incomplete ossification of the cuboidal bones, and juvenile arthritis.[9] *Chondrodysplasia* and *dyschondroplasia* are more descriptive terms because they imply a primary defect in cartilage maturation, but their use is generally reserved for abnormalities of limb and vertebral development. The terms osteochondrosis, osteochondritis, and osteochondritis dissecans have all been used synonymously in discussing the condition. To maintain consistency and avoid confusion, the following designations are used: *osteochondrosis* refers to the disease, *osteochondritis* refers to the synovial inflammatory response caused by the disease, and *osteochondritis dissecans* refers to the condition when a cartilaginous flap is identified.[10]

Osteochondrosis has been recognized in most domestic species, including horses, swine, and less often in cattle, sheep, and goats. The main focus has been in horses because of the economic impact and performance-limiting characteristics of the disease and in swine because of effects on production traits[11] and the development of comparative models for study of the disease.[12]

38.2.2 Clinical Signs and Differential Diagnosis

Osteochondrosis can present with a variety of clinical signs that are frequently recognized in juvenile animals. Effusion of the affected joint with or without accompanying lameness is common. The tarsocrural and femoropatellar joints are most often affected, but the condition can be seen in any joint. Physitis, or inflammation at the physeal plate, in young animals can have a similar appearance, with generalized enlargements adjacent to synovial structures. Osteomyelitis can cause a periosteal reaction that, if located in the area of a joint, can have a similar appearance. Septic arthritis can closely mimic the signs of osteochondrosis, but the associated lameness is often much more severe. Physitis, osteomyelitis, synovitis, and septic arthritis should all be considered in the differential diagnosis of osteochondrosis in juvenile animals. In older animals the clinician should consider synovitis, osteoarthritis, and trauma in the differential diagnosis.

Osteochondrosis is generally diagnosed in horses when they are started into training programs or begin athletic activity. They often present with a complaint of joint effusion that can be acute or insidious. Lameness is usually nonapparent to mild, except in cases with large osteochondral fragments or subchondral bone cysts. Severe cases seem to be more common in the stifle, and associated clinical signs may be present in foals as young as 6 months. Warmblood horses generally present later, at 3 to 4 years of age, because it is common practice to delay training until this stage.

Reports in cattle indicate that young, intact male, purebred animals are most often affected. The typical clinical signs are lameness with associated joint effusion. Osteochondrosis in swine has been associated with a syndrome known as “leg weakness.” Affected animals can show a range of signs, from mild lameness to

inability to rise and inability or refusal to mount.[13] Evaluation of performance data from swine herds can be a useful indicator of osteochondrosis because it has been shown to have a significant effect on production traits.[11,14] Cattle and swine are production animals slaughtered before 2 years of age, so clinical signs may only be recognized in purebred animals used for breeding purposes.

38.2.3 Sites of Predilection

Osteochondrosis can be found in any diarthrodial joint, but sites of predilection exist in all species affected. In horses the stifle and hock are most frequently affected. In the stifle, in order of frequency, the lateral trochlear ridge of the femur, medial trochlear ridge of the femur, trochlear groove, and distal end of the patella are affected.[15] The medial femoral condyle is the site of predilection for subchondral cystic lesions. In the hock, in order of frequency, the distal intermediate ridge of the tibia, lateral trochlear ridge of the talus, and the medial malleolus are affected.[15] Predilection sites in cattle are similar to those in horses, with the hock and stifle most often affected and similar distribution in the joints.[16] Swine show a slightly different pattern, with the medial condyle of the humerus and femur most frequently affected.[14]

38.2.4 Diagnostic Tests

Animals presenting with signs of joint effusion and lameness should undergo a thorough physical examination. Complete blood count (CBC) indicating a septic process along with radiography help differentiate osteomyelitis, septic physitis, or septic arthritis from osteochondrosis. In cases with any indication of a septic process, appropriate cultures should be taken. Horses should be observed in motion along with flexion tests, using local and intraarticular anesthesia to localize the site of lameness. Swine and cattle can be observed in their normal surroundings for signs of lameness. Once localized, the affected joint should be radiographed along with the corresponding joint on the contralateral limb in the tarsocrural and femoropatellar joints because the lesions are often bilateral in nature (Fig. 38-1). If lesions are detected in the metacarpophalangeal or metatarsophalangeal joint, the remaining three limbs should be radiographed because these can occur quadrilaterally.[17]

Lameness and effusion are more reliably seen in cases of osteochondritis dissecans and subchondral bone cysts than in osteochondrosis. Intraarticular anesthesia of the affected joint will alleviate the lameness, localizing the source. After the lameness has been localized, appropriate radiographs of the affected area should be obtained (Fig. 38-2), as well as of the contralateral or quadrilateral limbs, as described previously.

Swine and cattle will often present with signs of lameness and mild joint effusion. Careful physical examination of the restrained animal should allow localization of the affected area and appropriate radiographs to be obtained. As with equine patients, the lesions are rarely unilateral, and corresponding limbs should be radiographed. Reviewing production records of finishing or breeding swine herds may also be of diagnostic value because osteochondrosis has been shown to cause significant reductions in performance and production traits.[11]

Fig. 38-1 Osteochondrosis in the tarsocrural joint of a horse. Note the characteristic osteochondral fragments located at the distal intermediate ridge of the tibia.

The manifestations of osteochondrosis may not be adequately represented by clinical signs and radiographs. Clinical signs of lameness and joint effusion have been shown to precede changes within the joint, and serial radiographs may be needed to diagnose the condition.[18] Also, radiographic abnormalities consistent with osteochondrosis of the distal intermediate ridge of the tibia and lateral trochlear ridge of the femur can return to a normal appearance by 5 and 8 months, respectively, in warmblood foals.[19] Radiographs also often underrepresent the severity or size of the lesion seen at surgery.

38.2.5

Pathophysiology

Endochondral ossification is the process of bone formation that begins with a cartilage scaffold arranged in zones that are gradually replaced by bone. It occurs at the articular/epiphyseal and metaphyseal growth plates and secondary centers of ossification, such as the carpal and tarsal bones. Directly beneath the articular cartilage is a zone of resting chondrocytes that divide to form the next zone, the proliferating chondrocytes. These proliferative cells divide rapidly, organizing into columns perpendicular to the long axis of growth. The cells progress to the hypertrophic zone, where they swell and become vacuolated, and the columns become more organized. The chondrocytes in this zone also become surrounded by increasing amounts of extracellular matrix, which becomes mineralized in the zone of calcification. These columns of chondrocytes are invaded by metaphyseal blood vessels, and bone forms on these calcified cartilage columns, creating the primary spongiosa, which is subsequently remodeled into mature bone.

Fig. 38-2 Osteochondrosis in the femorotibial joint of a horse. Note the large subchondral cystic lesion in the medial femoral condyle, a typical location for these types of lesions.

The exact pathogenesis of osteochondrosis is still undefined. The traditional theory is that the process of endochondral ossification is disrupted, resulting in areas of thickened cartilage. The deeper layers of these retained cartilage plugs do not receive adequate nutrients by diffusion from the synovium, and necrosis of the cells develops. These areas of cartilage have less structural integrity than normal cartilage and are prone to damage. Shear forces acting on the abnormal cartilage can lead to fissure formation. These fissures can then form dissecting cartilage flaps, free flaps, or fragments of cartilage and subchondral bone. When compressive forces predominate on an area of thickened cartilage, it can cause infolding of the cartilage plug. Normal endochondral ossification proceeds around the infolded plug, forming a subchondral bone cyst.

This traditional theory of defective endochondral ossification is still well accepted, but recent literature suggests this may be a simplistic view of a multifactorial condition. Limited reparative responses of bone and cartilage make it difficult to determine whether the origin of a lesion is developmental or traumatic. A recent report failed to distinguish articular cartilage differences in naturally occurring osteochondrosis versus healing osteochondral fragments.[20] Arthroscopic observations of normal-thickness cartilage defects and normal subchondral bone, as well as lesions occurring preferentially at single sites at the limits of articulation, suggest causative factors other than defective endochondral ossification.[17] The development and spontaneous regression of osteochondrosis lesions suggest that the condition is a dynamic process that can be affected by numerous intrinsic and extrinsic factors, and a “window of susceptibility” may exist whereby lesions are repaired and normal articular development proceeds.[21] These findings and observations suggest that multiple pathologic pathways exist and that a single etiologic explanation of osteochondrosis is unlikely.

1191

1192

38.2.6 Etiology

As with the pathophysiology, the exact etiology of osteochondrosis is unclear and likely multifactorial in origin. Several factors, including biomechanical forces, failure of vascularization, nutrition, growth rate, genetics, and hormones, have been implicated and are likely interrelated in the etiopathogenesis of the disease.

The consistent distribution of lesions at specific anatomic sites within the joint implicate trauma as a causative factor. The bilateral or quadrilateral nature of the disease would indicate that trauma or biomechanical stress is a necessary factor rather than direct cause. It has been established in pigs that microtrauma or disruption of the blood vessels in the developing cartilage canals causes ischemic necrosis, failure of mineralization, and a retained cartilage plug.[22] This mechanism has not been elucidated or studied in horses or cattle; therefore, while offering a plausible explanation, the results cannot be applied across species lines.

Nutritional influences have been extensively studied in relationship to osteochondrosis. The studies have focused mainly on dietary energy levels and mineral composition (copper and zinc). The growth rate of the animal is directly affected by energy intake as well as the genetic predisposition of the animal for growth and size. Animals fed high-energy levels for accelerated growth rates have a much higher incidence of osteochondrosis than those fed for lower rates of growth.[12,23,24] Low copper levels and increased zinc concentrations have both been implicated in the etiology of the disease. Low copper is thought to exert its effect through lysyl oxidase, a copper-dependent enzyme essential in the cross-linking of collagen molecules. Increased levels of zinc antagonize copper and could work indirectly through a similar mechanism. There is conflicting evidence on the causative nature of low copper levels, and lesions seen in copper-deficient animals do not always mimic those of naturally occurring osteochondrosis. More recently, evidence suggests that neonatal copper levels exert a positive effect on the resolution of osteochondrosis lesions but are not directly involved in the pathogenesis of the disease.[25]

Genetics have been shown to be at least partially responsible in the etiopathogenesis of osteochondrosis in different species. Landrace and Yorkshire breeds of swine show a high frequency of osteochondrosis, whereas domestic pigs crossed with wild hogs do not develop the disease.[12] Heritability has also been demonstrated in standardbred trotters in the tibiotarsal and metacarpal/metatarsal phalangeal joints.[26,27] A genetic component may also be related to nutrition levels because an animal must have the genetic capacity for increased growth rates and size while at high planes of nutrition.

Alterations in hormone concentrations have been implicated in the etiology of osteochondrosis, but the mechanisms remain in question. Numerous hormones, such as insulin, somatotropin, and thyroxine, are involved in the process of endochondral ossification. Physiologic or iatrogenic alterations of these hormones or their derivatives could theoretically lead to the development of osteochondrosis. The contribution of these factors to the etiology of osteochondrosis will likely not be elucidated until the molecular mechanisms of endochondral ossification are better understood.

38.2.7 Treatment and Prognosis

The treatment of osteochondrosis should take into account several factors. The clinical signs; severity of the lesion; species, age, intended use, and relative value of the animal; and owner expectations should all be considered. Treatment options include both nonsurgical and surgical management.

Nonsurgical management should consist of rest, controlled exercise, and dietary evaluation. The mineral and carbohydrate levels of the diet should be evaluated carefully and any deficiency or excess corrected. Systemic NSAIDs and intraarticular medications such as corticosteroids, hyaluronic acid, and polysulfated glycosaminoglycans (GAGs) can all be administered, but minimal clinical evidence exists to support their use. In food-producing animals the clinician must take into consideration that these are not approved treatments and that withdrawal times may not be established. Given the nature of the disease, nonsurgical management may provide a favorable outcome only in very young animals with regenerative capacity or in those with very mild lesions and minimal to no clinical signs.

Animals with osteochondritis dissecans are best treated with arthroscopic surgery. Cases with no radiographic evidence of degenerative joint disease (DJD) before surgery and minimal articular damage at arthroscopy carry a favorable prognosis. Animals that show radiographic evidence of DJD before surgery or considerable damage to the articular surfaces at arthroscopy carry a guarded prognosis. Arthroscopic approaches to the joints of cattle have been described, but the procedure is more difficult than in the horse.[16] In select cases, reattachment of large cartilage flaps with absorbable poly-*p*-dioxanone pins may be warranted.[28] Diet evaluation should be included with the surgical patients and appropriate adjustments made.

Treatment of subchondral cystic lesions is still controversial, and many options are available. Nonsurgical management can be attempted and should consist of rest, controlled exercise, and intraarticular injection of corticosteroids along with hyaluronic acid or polysulfated GAGs. The prognosis is guarded except in cases with very narrow openings into the synovial cavity, and alternate treatments should be considered in refractory cases. Cysts can be treated with ultrasonographically or arthroscopically guided intralesional deposition of corticosteroids, bone marrow aspirates, or a combination of the two. Studies are lacking as to the efficacy of this treatment. Arthroscopic debridement and curettage of the cystic lesion is another option, and horses less than 3 years of age carry a better prognosis. Recent investigations show promise for arthroscopic debridement and curettage of lesions followed by packing of the remaining defect either with a cancellous bone graft

covered by a chondrocytic growth factor or with various bone substitutes.[28] Cysts located in the proximal interphalangeal joint are generally nonresponsive to conventional treatment, and arthrodesis of the joint offers the best prognosis.

Treatment of osteochondrosis in food animals is generally limited by the economic value of the animal. Show animals or valuable breeding animals may be treated by any of the methods previously described, and the surgical options will offer a better prognosis than nonsurgical treatment. In production herds, ration evaluation and genetic predisposition may be the only variables that can be addressed. A review of production records and estimates of monetary loss will indicate whether intervention is necessary.

38.3 ANGULAR LIMB DEFORMITIES

JEFFREY P. WATKINS

38.3.1 Definition, Etiology, and Clinical Signs

Angular limb deformities are deviations in the axis of the forelimbs or hindlimbs in the frontal plane. *Valgus* deformity denotes a lateral deviation of the limb distal to the origin of the deformity; *varus* deformity denotes a medial deviation. The deformity is further described by naming the joint adjacent to the origin of the deformity; for example, carpus valgus describes an angular deformity arising in the carpal region with lateral deviation of the metacarpus (knock-kneed conformation) (Fig. 38-3).

Angular limb deformities may be either congenital or acquired. In general, they are caused by laxity of periarticular supporting structures, incomplete ossification, or asynchronous growth rate. Although the underlying cause of these abnormalities remains undefined, potential causes include intrauterine malpositioning, relative immaturity, hereditary predisposition, rapid growth, dietary imbalances, osteochondrosis, and trauma.[29–31]

Congenital angular deformities frequently are attributed to intrauterine malpositioning and laxity of periarticular supporting structures. They typically originate in the region of the carpus and tarsus, resulting in bilateral valgus deformity. It is also common to identify a “windswept” foaling in which valgus deformity of one limb is accompanied by varus deformity of the contralateral limb. Acquired angular deformities usually occur secondary to asynchronous growth. Additionally, a foal born with incomplete ossification may acquire an angular deformity secondary to crushing of the cartilaginous precursors of the cuboidal bones. A hereditary angular limb deformity of Suffolk, Suffolk crossbred, and Hampshire sheep is known as spider lamb syndrome (see later discussion).

Fig. 38-3 Carpus valgus deviation.

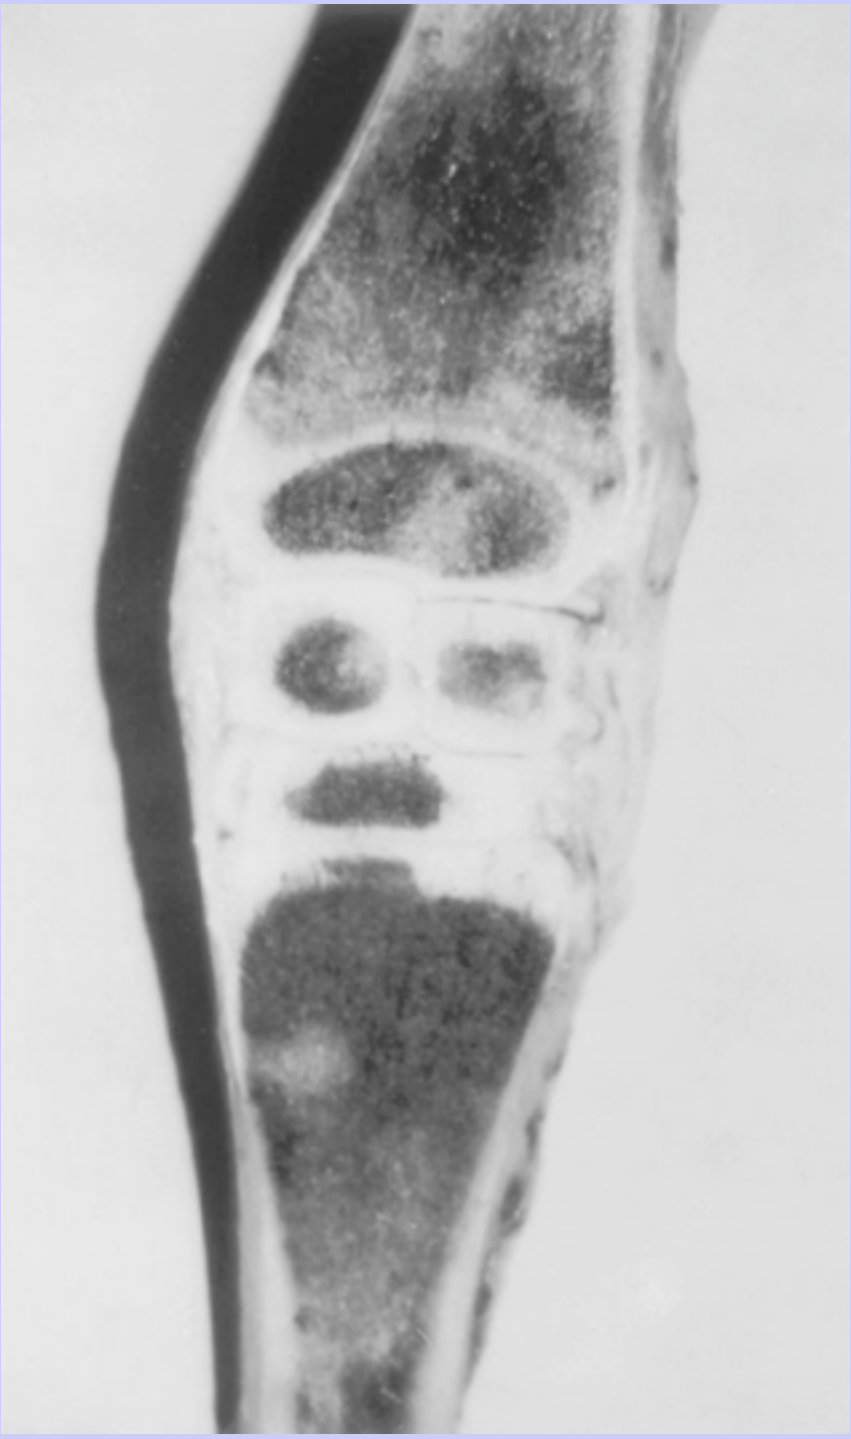
38.3.2 Pathophysiology

Incomplete ossification is an important cause of angular deformities originating at the carpus and tarsus. The epiphyses and cuboidal bones of the carpus (ulnar, third, and fourth carpal bones) and tarsus (central and third tarsal bones) are primarily affected.[29] Ossification of the cartilaginous precursors of these bones occurs in late gestation; prematurity or relative immaturity results in the birth of a foal before these precursors are completely ossified (Figs. 38-4 and 38-5). If laxity of the periarticular supporting structures accompanies incomplete ossification, the deformity is congenital and may progressively worsen with weight bearing. If laxity is not present, the foal may be born with straight legs and may acquire an angular deformity after deformation of the precursors of the cuboidal bones during weight-bearing activity.

Foals can acquire an angular limb deformity as a result of asynchronous growth at the metaphyseal and epiphyseal growth cartilages.[30,31] An important cause of asynchronous growth is trauma to a portion of the growth cartilage of the physis.[32] In many foals this trauma is in the form of nonphysiologic compression of the growth cartilage. Excessive exercise in foals with mild angulation and normal activity in foals with moderate to severe preexisting angular deformity may cause sufficient trauma to the growth cartilage to cause progressive deformity.

Fig. 38-4 Premature foal with incomplete ossification of the cuboidal carpal bones showing marked bilateral carpus valgus.

Fig. 38-5 Specimen from a foreleg of the premature foal in Figure 38-4, cut in the frontal plane. Note the thick cartilage surrounding the centers of ossification of the cuboidal carpal bones.



Asymmetric loading also occurs when severe lameness is present. With the change from a rectangular stance with four weight-bearing limbs to a triangular stance with three weight-bearing limbs, asymmetric, nonphysiologic loading of the weight-bearing limb occurs, which predisposes it to develop an angular deformity. Because compressive forces are concentrated along the medial aspect of the growth cartilages, a varus deformity usually develops in the overloaded limb. Abnormalities of the growth cartilage that affect ossification, such as osteochondrosis, also may be responsible for angular deformities caused by asynchronous growth. Foals with a predisposition for rapid growth or those that are exposed to nutritional imbalances appear to be at greatest risk for developing the disease. Rapid growth also may result in a foal with a large body size disproportionate to its skeletal structures. This condition may cause increased compressive forces, nonphysiologic loading of the growth cartilages, and angular deformity.[32]

Ruminants raised in confinement may experience endochondral dysplasia and angular limb deformities if dietary iron is high or dietary vitamin D is low[33] (rickets). Elevated dietary iron results in elevations in serum phosphorus, which may in turn inhibit 1,25-dihydroxycholecalciferol synthesis by the kidney, resulting in rickets.[33] Pregnancy-associated epiphysitis in primiparous dairy goats[34] also may result in angular limb deformities.

38.3.3 Evaluation and Radiographic Findings

In the evaluation of a foal with an angular deformity, important historical information includes age, onset and progression of the deformity, and intended use of the foal. The foal should be observed carefully while standing and walking to characterize the degree of deformity and determine the presence of compensatory problems or lameness. Physical examination includes careful palpation of the affected limb and a determination of whether the deformity can be corrected by manual manipulation of the limb. If the foal is examined before ossification has progressed, deformities resulting from laxity of periarticular supporting structures and incomplete ossification can be corrected manually. On the other hand, if deformities in foals born with incomplete ossification are left untreated and the cuboidal bones are in a collapsed configuration, or if deformities are the result of asynchronous growth, they cannot be corrected manually.

An arthropathy should be suspected if lameness is present. Collapse of incompletely ossified cuboidal bones may result in deformation of articular surfaces and subsequent DJD. When this occurs in the carpus, the prognosis for athletic performance is guarded to poor. If the cuboidal bones of the tarsus are affected, mild collapse may not adversely affect performance, but with significant collapse, degenerative change is likely. A less common cause of lameness in foals with angular limb deformity is osteochondrosis. The prognosis for athletic performance in foals with osteochondrosis-associated angular limb deformities is guarded, depending on the severity of the cartilage lesions.

The importance of early radiographic evaluation of foals with angular deformity cannot be overemphasized. If a diagnosis of incomplete ossification is delayed, irreparable damage, as described previously, may occur. In fact, a strong argument can be made for radiographic evaluation of all foals shortly after birth before uncontrolled exercise is allowed. Radiographic evaluation is mandatory to determine the degree of ossification in premature foals, twins, foals that appear to be relatively immature at birth, and foals born with angular deformities.

Radiographic evaluation allows the examiner to identify the origin of the deformity and determine its severity. Dorsopalmar views for the carpus and fetlock using 7 × 17–inch film cassettes and a lateromedial view of the tarsus are recommended. In the carpus and fetlock the origin of the deformity may be subjectively determined by two geometric methods (Fig. 38-6). One is to draw longitudinal lines bisecting the long bones above and

below the joint. Where these lines intersect is the *pivot point,* which is considered the origin of the deformity. In addition, the angle of incidence of these lines is an estimation of the degree of deformity. Another method, which the author prefers for the carpus and fetlock, is to draw lines through the joints and adjacent physes. These lines should be parallel to each other and perpendicular to the long axis of the long bones proximal and distal to the affected joint. The origin and degree of deformity are estimated by determining where and by what degree these lines deviate from normal. Both asynchronous growth and incomplete ossification can occur concurrently, which is most easily determined with the latter method of geometric evaluation[29] (Fig. 38-7). Geometric examination to determine the degree of deformity in the tarsus is less reliable because the tibia and third metatarsus are not in the same frontal plane. The severity of the angular deformity in this location is best determined by a careful visual assessment.

Radiographic examination of foals with incomplete ossification reveals a rounded contour to the affected bones instead of their normal angular appearance. The width of the radiolucent cartilage is increased, appearing radiographically as an increase in the width of the joint space (Fig. 38-8). As ossification progresses, the bones may appear wedge shaped or crushed because of deformation of the cartilage during weight bearing. This phenomenon often is noted in the ulnar, fourth, and lateral aspect of the third carpal bones in the forelimb and the central and third tarsal bones in the hindlimb. In severe cases the affected bones may be grossly deformed and appear to be partially extruded from the joint (Fig. 38-9). In the tarsus, lateromedial radiographs are used to determine whether ossification is complete (Fig. 38-10).

Fig. 38-6 Two methods for geometric evaluation of an angular deformity at the carpus. Lines *A* and *B* are drawn through the long axis of the radius and metacarpus, respectively. The angle of incidence is 15 degrees. Lines *a, b, c* and *d* are drawn through the distal radial physis, antebrachiocarpal (radiocarpal), middle, and carpometacarpal joints, respectively. Line *a′* is drawn parallel to line *b*, and line *a″* is perpendicular to *A*. Their angle of incidence is 15 degrees. *Reprinted with permission from* Compend Cont Educ (Pract Vet)*4:S330, 1982*.

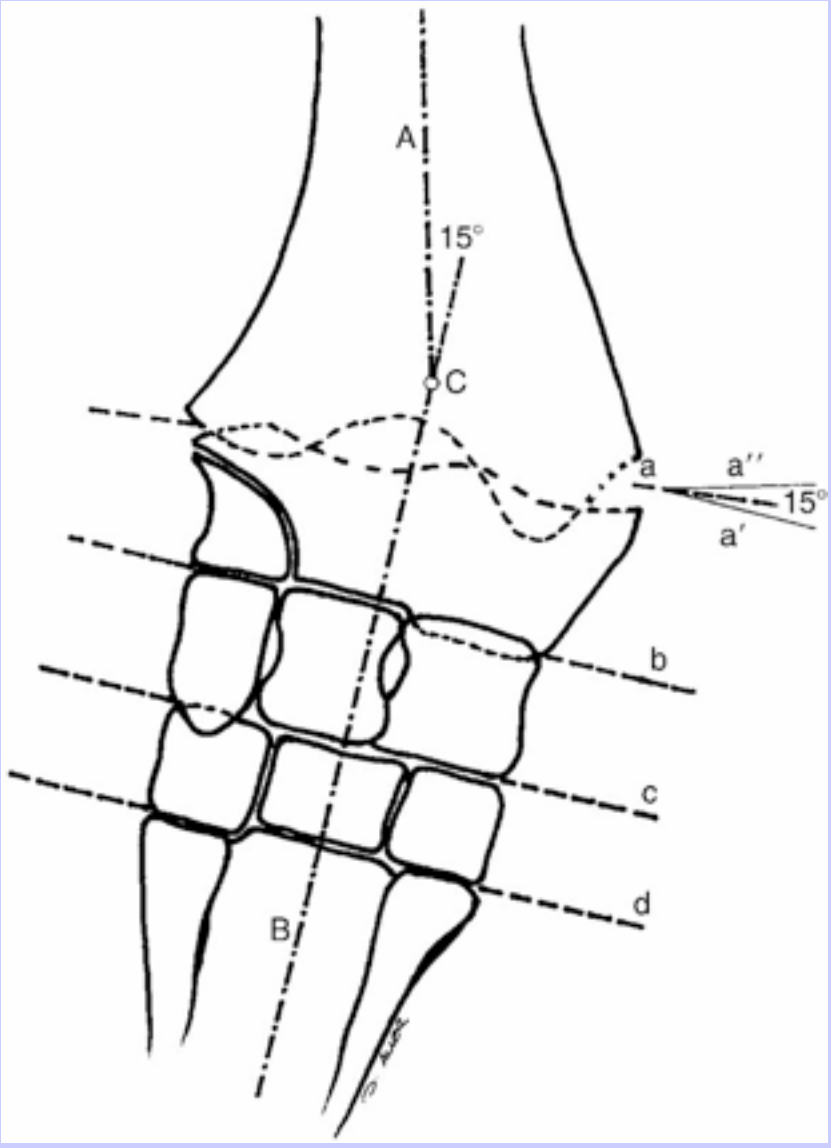


Fig. 38-7 Geometric evaluation of an angular deformity at the carpus caused by a combination of asynchronous growth and incomplete ossification. The pivot point, *c,* identified by lines *A* and *B,* indicates that the origin of the deformity is in the distal radial epiphysis. However, lines *a, b, c* and *d* are not parallel to each other; and lines *a, b* and *c* are not perpendicular to the long axis of the metacarpus and radius. Their orientation indicates that the deformity is in the distal radial physis and the cuboidal carpal bones as well. Note that the sum of angles of *a-a′, b-b′*, and *c-c′* equals the angle of incidence of lines *A* and *B*. *Reprinted with permission from* Compend Cont Educ (Pract Vet) *4:S330, 1982*.

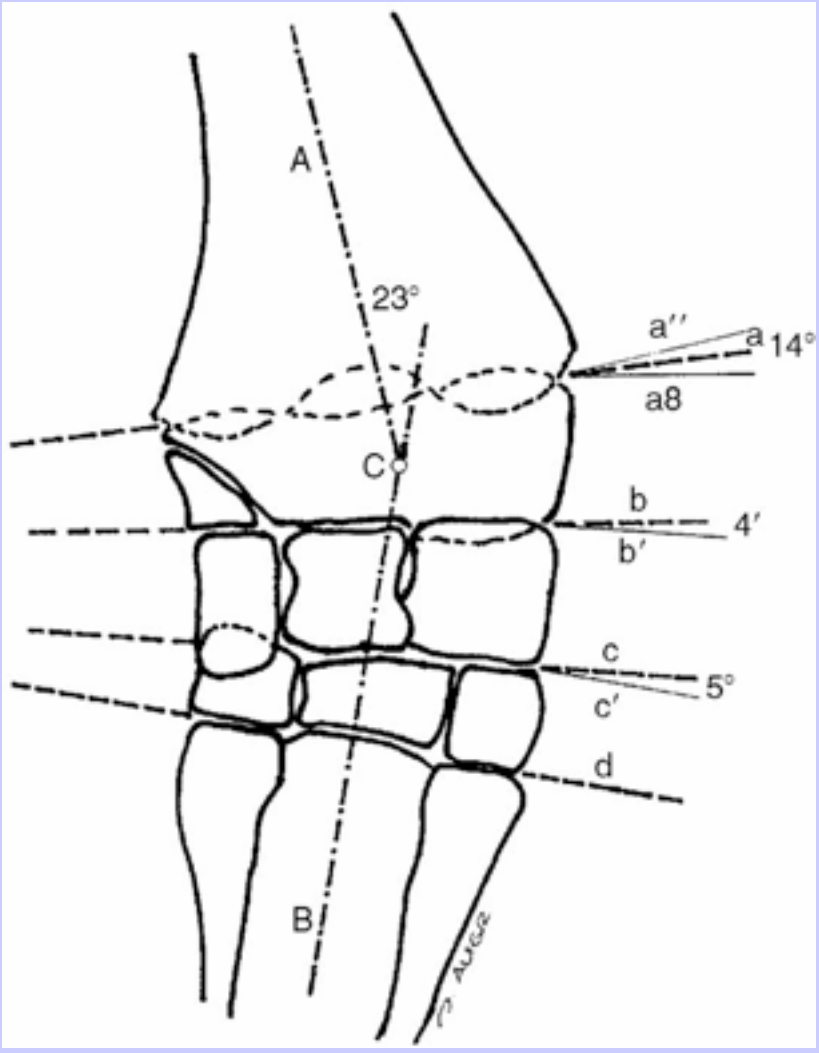

Fig. 38-8 Dorsopalmar radiograph of a foal with mild incomplete ossification of the cuboidal carpal bones. Note the difference in width of the medial aspect, *a,* and the lateral aspect, *b,* of the third carpal bone. Normally, width *a* should be approximately three-fourths the width of *b*.[41] Also note the appearance of an increase in the width of the joint space, *c,* as a result of incompletely ossified joint cartilage.

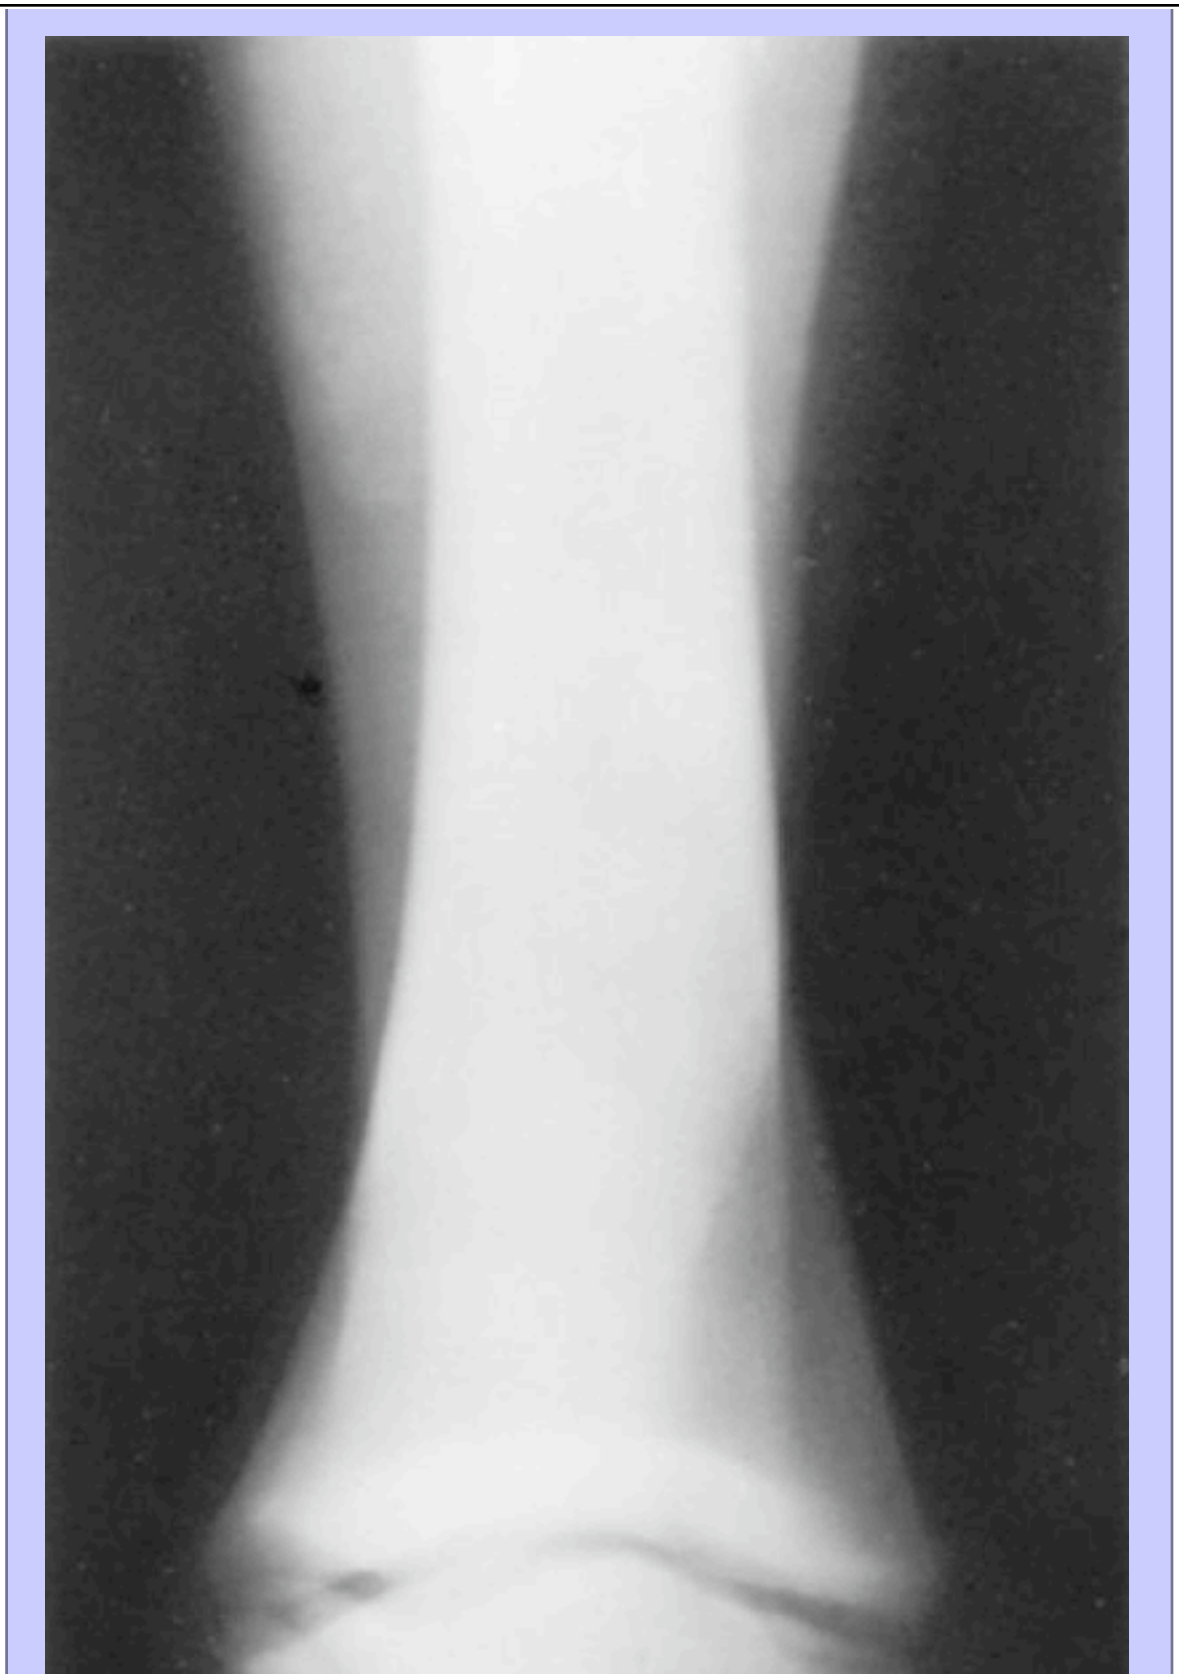


Radiographic evaluation of foals with angular deformity caused by asynchronous growth may show wedging of the epiphysis (Fig. 38-11), widening of the physis, and sclerosis adjacent to the physis. Geometric evaluation places the deviation in the metaphysis or the epiphysis of the long bone proximal to the affected joint. The joints are parallel each other and are perpendicular to the longitudinal axis of the adjacent long bones.

38.3.4 Treatment and Prognosis

Neonatal foals with an angular deformity should be confined to a stall until clinical and radiographic examinations are completed. If the deformity is 10 degrees or less and radiographs reveal normal ossification, stall confinement with periods of controlled exercise is recommended. This regimen promotes continued development of the supporting structures while minimizing trauma to growth cartilages that could result if the foal were allowed uncontrolled exercise.

1195
1196

Fig. 38-9 Dorsopalmar radiograph of a foal with incomplete ossification that was not externally supported. Severe deformation and collapse of the fourth and third carpal and proximal fourth metacarpal bones have occurred.

Foals with a congenital angular deformity of more than 10 degrees accompanied by incomplete ossification or ligamentous laxity failing to improve with controlled exercise should be externally supported. If incomplete ossification is present and the limb is not supported in axial alignment, continued weight bearing can cause deformation of the cartilaginous structures. Subsequent ossification results in a permanent deformity of the affected bones (see Fig. 38-9).

Methods of externally supporting the carpus and tarsus vary from the application of tube casts or rigid splints to custom-made orthotic devices. Tube casts have been recommended and used successfully for several years.[29–31] Although tube casts provide the rigid external support needed to maintain axial alignment while ossification progresses, several potential complications are associated with their use. The most serious complication is the potential for coxofemoral luxation when tube casts are used on the hindlimbs. In addition, foal skin is easily traumatized by a poorly fitting cast, and deep ulcerations may occur. Other considerations include the cost of materials and need for constant monitoring to detect signs of a poorly fitting cast. Monitoring the status of a cast requires daily evaluation by a trained individual, and owners are seldom capable or willing to take on this responsibility; therefore hospitalization is recommended. Rigid splints are an alternative method of support. The leg is protected with a padded support bandage, and the splint is applied with nonelastic tape while the limb is held in alignment by an assistant. These splint bandages are changed every third or fourth day. Pressure sores beneath the splint bandage are a concern and must be prevented. A splint for the tarsus may be fashioned from synthetic casting material molded lengthwise over the cranial aspect of a padded bandage centered at the joint. Once the material has dried, the splint is taped to the dorsal surface of the bandage.

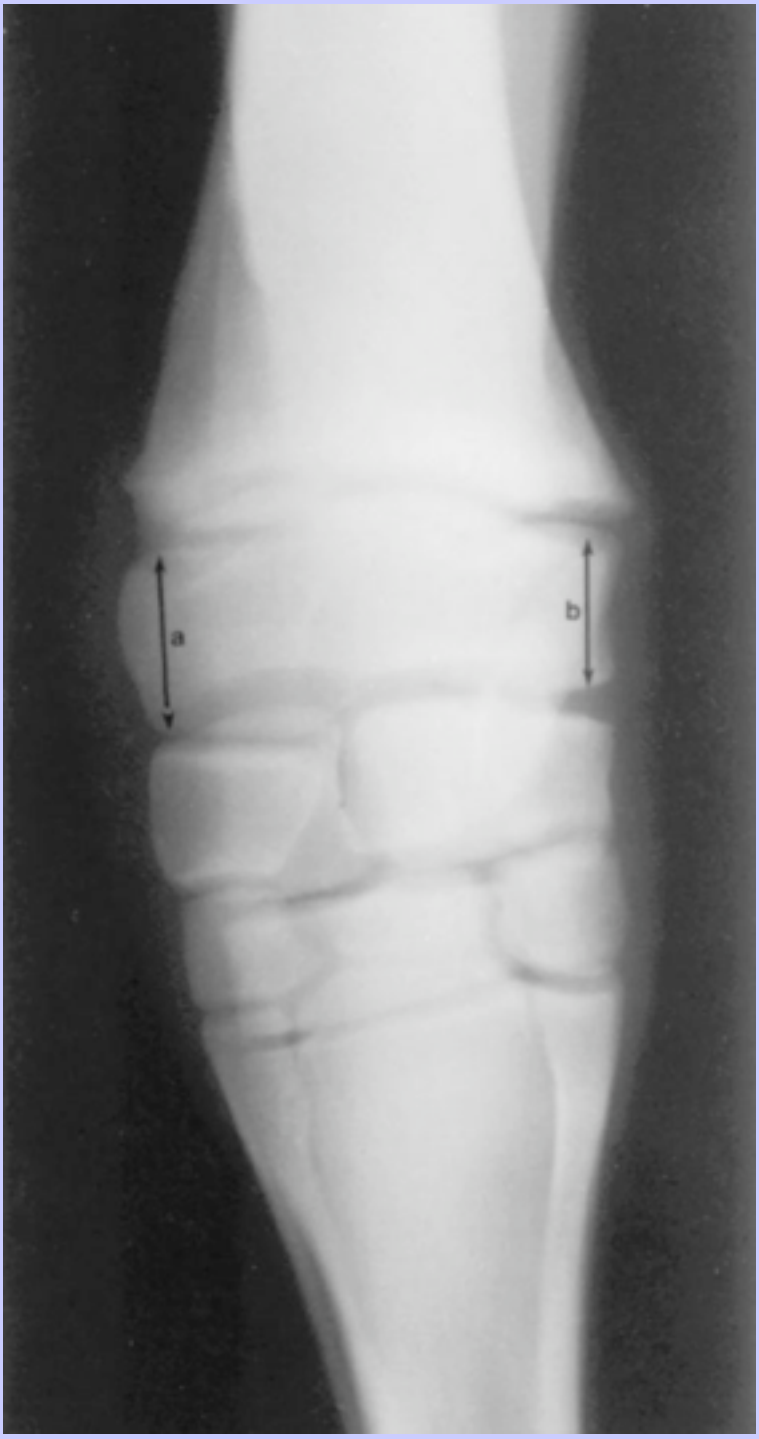
Fig. 38-10 Lateral-to-medial radiograph of a tarsus from a foal with incomplete ossification. Note the lack of an angular appearance of the central tarsal bone and incomplete ossification of the third tarsal bone.

Regardless of the means of external support used for the carpus or tarsus, it should not extend beyond the distal metacarpus or metatarsus. Continued weight bearing by the suspensory apparatus of the fetlock helps prevent the development of fetlock hyperextension after removal of the external support. A degree of carpal hyperextension is usually present immediately after removal of external support from the forelimb, and exercise should be controlled until the tendons and periarticular supporting structures regain their normal tone.

Foals with angular deformity resulting from asynchronous growth should also be confined to a stall and allowed only controlled exercise to minimize the magnitude of asymmetric loading at the growth cartilages and encourage spontaneous correction. In these cases, reducing the magnitude of the forces acting asymmetrically at the growth cartilage should encourage compensatory growth to occur and correct the deformity. Additional therapy consists of corrective hoof trimming. Because foals with valgus deformity typically have a toe-out conformation, emphasis in the past has been to lower the lateral hoof wall of the affected limb. If this mode of therapy is vigorously pursued, compensatory varus deformity may develop in the fetlock region. This form of corrective trimming concentrates forces asymmetrically on the medial aspect of the distal metacarpal and proximal phalangeal growth cartilages. Currently, trimming the hoof level and squaring the toe to promote breakover at the toe are recommended. If the lateral hoof wall is to be lowered; only a few millimeters should be removed each week.

1196
1197

Fig. 38-11 Dorsopalmar radiograph of a foal with angular deformity caused by wedging in the distal radial epiphysis, the result of asynchronous growth of the epiphyseal growth cartilage.



Foals with angular limb deformities that fail to respond to stall confinement are candidates for surgical therapy. Although it was previously believed that animals with angular deformities arising distal to the physis were not candidates for surgical therapy, it has been shown that they can respond favorably to surgery.[35,36]

The decision for surgery should take into account the amount of correction required (degree of deformity) and the age of the foal. The more severe the deformity, the earlier should be the surgical intervention. Timing of surgery should consider the periods of rapid and predictable growth at the physis. The most rapid and predictable rate of growth occurs from birth to 10 weeks of age.[37] In the distal radius, continuous but declining growth occurs until 60 weeks of age. In the distal third metacarpal and metatarsal bones, growth rate slows dramatically by 10 weeks of age and stops shortly thereafter.

Surgical manipulation of physeal growth is intended to alter asymmetrically the elongation occurring at the physis, thereby realigning the axis of the limb. Growth at the physis can be altered surgically in one of two ways: retardation or acceleration. *Growth retardation* is accomplished by bridging the physis with metallic implants. When applied to the convex side of the affected physis, growth is disallowed on the long side of the bone while continued growth on the opposite of the bone brings the limb into alignment. As long as the implants are in place, the effect continues and is limited only by the amount of growth remaining at the physis. If the physis is still active once the limb is aligned, it is extremely important that the implants be removed, or overcorrection will occur. Techniques of transphyseal bridging include stapling, screw and wire implants, the use of a small bone plate, and more recently, a single transphyseal screw. Indications for transphyseal bridging include deformities that present after the period of rapid and reliable physeal growth, severe angulations, and based on the author's experience, deformities of the carpus and tarsus resulting from cuboidal bone malformations.

In the second surgical approach to altering physeal growth, periosteal transection and elevation (stripping) is aimed at promoting *growth acceleration* on the concave side of the bone.[38] Reported advantages include rapid correction without the potential for overcorrection.[35,38] Periosteal transection does not require implants; therefore the likelihood of infection and excessive fibrosis is reduced. Implant failure is not a consideration, and a second surgery for implant removal is not required. The procedure does not require specialized equipment and is technically easy to perform. In one series of foals, correction of the deformity occurred in 22 of 25 limbs treated with periosteal transection.[38] In a second series of 23 foals, 83% had straight limbs and were sound for their intended use at long-term follow-up.[35] The success rate was not affected by the origin of the deformity, degree of deviation, or presence of mild to moderate morphologic changes in the involved bones.[38] Indications include mild to moderate deformities present during the rapid, reliable growth at the involved physis. The periosteum will reestablish itself, so the surgical effect is short-lived, and if correction is not adequate within 4 to 6 weeks, additional therapy is indicated.

38.4 SPIDER LAMB SYNDROME (OVINE HEREDITARY CHONDRODYSPLASIA)

NANCY EAST

By the mid-1980s, multiple reports from all areas of the United States were documenting the occurrence of Suffolk lambs with skeletal abnormalities, commonly called “spiders,” “spider lambs,” “corkscrew lambs,” “monkey lambs,” “crooked lambs,” and “bent lambs” by producers. Simultaneously in several university-owned Suffolk sheep flocks, lambs were born affected with the spider syndrome, and research began to describe and characterize the syndrome.[39]

38.4.1 Definition and Etiology

Spider lamb syndrome is characterized by generalized chondrodysplasia and is apparently a semilethal autosomal recessive trait. Variable expressivity of the trait may occur in the homozygous animal.[40–42] It has been seen in Suffolk, Suffolk crossbred, and Hampshire sheep (Hampshire sheep often have some Suffolk breeding). At this time, no chondrodysplastic lambs from any white-face breeds of sheep have been reported.

38.4.2 Clinical Signs

1197
1198

Lambs affected with spider lamb syndrome are characterized by overall appendicular and axial deformities, including one or more of the following conditions[40,42]: kyphosis, scoliosis, concavity of the sternum, lateroventral deviation of the maxilla (crooked nose and Roman nose), and angular limb deformities. The limb deformities usually include a "knock-kneed" appearance at the carpus (carpus valgus) and lateral deviation with rotation of the metacarpus or metatarsus (Fig. 38-12). In addition, these lambs show extreme height, fineness of bone, poor muscling, and failure to thrive (Fig. 38-13).

The number and severity of the deformities seen in individual lambs vary widely. Spider lamb syndrome can occur in two types of lambs: those that are obviously abnormal at birth and, more often, those that develop abnormalities at 3 to 8 weeks of age. Lambs that are abnormal at birth may have kyphosis, scoliosis, facial deformities, deformed sternum, and angular limb deformities.[40] Lesions may be present as early as day 100 of gestation but are not detectable by radiographic or ultrasound examination.[42] The lambs may be stillborn or die within a few days of birth because of their inability to stand or nurse. If these lambs are maintained by good nursing care, they fail to gain weight normally and usually die of secondary problems (e.g., scours, pneumonia) by 4 weeks of age. In lambs that are apparently normal at birth but develop angular limb deformities at 3 to 8 weeks of age, one to four limbs may be affected; and close examination may show curvature of the spine and concavity of the sternum. Often these lambs are unusually tall, long necked, fine boned, and poorly muscled. The growth rate of these "spider lambs" decreases after 4 to 8 weeks of age, and the various deformities become more marked until the lambs can no longer walk; chronic bacterial pneumonia and pathologic fractures are common.

Fig. 38-12 Rotation and deviation of front legs (carpus valgus) characteristic of spider lamb syndrome in a 16-week-old Suffolk lamb.

Fig. 38-13 Twin Suffolks (12 weeks old), with normal lamb (78 pounds) at left and lamb with spider syndrome (37 pounds) at right. Note extreme height, narrow chest, scoliosis, kyphosis, and facial deformity of affected lamb.

Attempts to maintain spider lambs for research are rarely successful beyond 6 months to 1 year of age. In Illinois an affected ram lamb was able to breed seven ewes before he died, but in California, two affected ram lambs failed successive semen evaluations from 7 to 12 months of age and were euthanized because of their poor condition.

38.4.3 Diagnosis

Currently, spider lamb syndrome is diagnosed on the basis of appearance, radiographic changes, and pathology (gross and microscopic). Radiographic changes are diagnostic, although serial radiographs may be necessary in some cases. There are widened, irregular growth plates with retained islands of cartilage in the olecranon, sternum, shoulder, long bones, and spine (Fig. 38-14). The most constant radiographic lesion is in the olecranon, which exhibits multiple islands of ossification instead of the uniform, nonmineralized cartilage surrounded by dense bone in a normal lamb.[40,43] The olecranon should be radiographed lateral to medial with the elbow flexed. The changes in the olecranon usually begin by 1 to 3 weeks of age and are progressive.

1198

1199

Lambs that are stillborn or die in the first week of life may not exhibit radiographic abnormalities in growth plates associated with spider syndrome.

Fig. 38-14 Lateral radiograph of front leg of a lamb with spider syndrome. Note thick, irregular growth plates and multiple ossification centers near the olecranon and distal humerus.

Chromosomal evaluation, hematology, and standard serum chemistry, as well as morphologic and biochemical evaluations of growth plate, have not been abnormal in spider lambs.[42–44] Circulating levels of insulin-like growth factor type I (IGF-I) and its associated hepatic messenger ribonucleic acid (mRNA) are increased in very young spider lambs. The proliferative zone of the growth plate is a major target of IGF-I.[45]

Differential diagnosis includes other diseases that result in congenital defects (scoliosis, kyphosis, and arthrogryposis, often associated with hydranencephaly), including Cache Valley virus, bluetongue virus, lupine ingestion, and the bent leg syndrome.[40,43] The bent leg syndrome is believed to be a dietary problem in young lambs suckling ewes on unimproved pasture; chondrodysplasia of the elbow is not present.

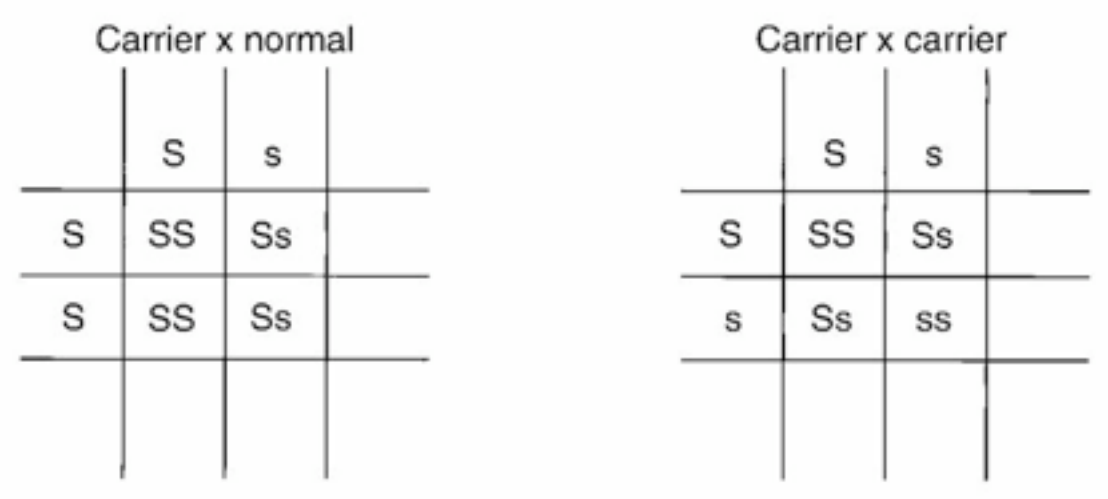
38.4.4 Epidemiology

Limited breeding trials, pedigree analysis of breeding stock producing "spiders," and the wide geographic distribution of spider lambs indicates that the spider syndrome is an inherited defect and is probably an autosomal recessive gene.[41,42] Some workers believe that the selection for very tall sheep within the Suffolk breed resulted in selection for the recessive trait. Affected lambs are double recessive (ss), and both the parents must be carriers (heterozygotes Ss) to produce a spider lamb (Fig. 38-15). Carrier sheep appear to be fairly common within the seed stock of the Suffolk breed and presently can be identified only when they produce a spider lamb. The appearance of a clinically affected lamb may lag years behind the introduction of carrier breeding stock, especially if a carrier ram is crossed into a ewe flock free of the trait. It is important that the diagnosis of a spider lamb is made correctly and with care, particularly in lambs that die before 3 weeks of age, because the condition may be confused with other congenital defects causing scoliosis, kyphosis, and arthrogryposis. Not all lambs suspected as being spider lambs can be confirmed as such.

38.4.5 Necropsy Findings

Gross postmortem examination findings are similar to radiographic changes (generalized chondrodysplasia). Joint cartilage may show erosion, and excess cartilage is evident in thickened, irregular growth plates and in the olecranon. Retained cartilage cores are apparent on the metaphyseal side of affected growth plates. Dysplastic growth plates of spider lamb syndrome are characterized by thickened, proliferative, and hypertrophic zones and a failure to form organized columns. Histologically, chondrocytes exhibit a chaotic pattern of ossification, with chondrocyte proliferation in areas of maturation and loss of normal pattern and direction.[40,44]

Fig. 38-15 Spider syndrome is believed caused by an autosomal recessive trait. This figure illustrates probable mode of inheritance in two possible matings that could produce spider lambs. *SS,* Normal; *Ss,* carrier; *ss,* affected.



38.4.6

Prevention and Control

Carrier rams should be destroyed, but carrier ewes can be used to produce market lambs or to progeny-test rams for the spider trait. Ram lambs produced from carrier ewes must not be used for crossbreeding on commercial ewes of any breed, except for terminal cross-market lambs, because crossbred Suffolk lambs can carry the trait into the commercial sheep industry. A ram can be progeny-tested by breeding to ewes that have produced spider lambs or by breeding to its own daughters. If a ram produces 16 normal offspring from matings with known carrier ewes or 32 normal offspring from mating with his own daughters, the probability that he is a carrier is less than 1 in 100. This procedure is costly to the breeder, and the temptation to retain a ram without an adequate number of test progeny is great. Rams that have enough normal progeny to reduce the probability of being a carrier to less than 5 in 100 have produced spider lambs from the next test breedings needed to complete the progeny test.* Within the purebred industry, breeding stock is classified as “white” (no known spider progeny), “gray” (sire or dam or sibling has produced a spider lamb, but this individual has not), or carrier or “black” (individual has produced a spider lamb). Inaccuracies in sheep pedigrees make prediction of the genetic makeup of any individual risky, and classification without proper testing may be potential grounds for legal action. If parentage of a spider lamb is in question, blood-typing of the sire, dam, and offspring may be helpful.†‡

38.5 SEPTIC (INFECTIOUS) ARTHRITIS AND OSTEOMYELITIS

JOANNE HARDY

38.5.1 Incidence and Risk Factors

Septic arthritis can result from extension of a periarticular wound infection, traumatic inoculation, iatrogenic inoculation, or hematogenous inoculation. The hematogenous route is the most common avenue of inoculation of organisms in a joint in foals, and bacteremia and septicemia are the most important risk factors for septic arthritis in foals. In one study, septicemia was the most common cause of death (30%) in foals under 7 days of age; septic arthritis was identified as the cause of death in 12.5% of foals age 8 to 31 days.[46] In adults, articular wounds are reported to be the most common cause of joint infection, followed closely by iatrogenic intraarticular injection; postsurgical infection and idiopathic (unidentified cause) are also reported in association with septic arthritis in adult horses.[47,48] Although uncommon, hematogenous spread from a distant focus is possible in adult horses.

Establishment of infection depends on several factors, including size of inoculum, host defense, virulence of the organisms, and local joint factors. In foals, host defense is mainly associated with passively acquired immunity. *Failure of transfer of passive immunity* (FTPI) is the greatest risk factor for development of septicemia in foals.[49] The incidence of disease resulting from FTPI has been reported to be as high as 78%. Organism virulence is related to the ability to establish infection. Attachment factors, ability to resist phagocytosis, and resistance to cell killing all contribute to the establishment of infection. Local joint factors that may predispose to establishment or maintenance of infection include low blood flow, particularly in end-loop capillaries, and poor blood supply, more prominent in bone. In adults, certain intraarticular medications (e.g., corticosteroids, hyaluronate, polysulfated GAGs) have been associated with a higher risk for septic arthritis, potentially by decreasing articular defense.[50,51]

In calves, septic arthritis is associated with FTPI and septicemia and with feeding of mastitic milk *(Mycoplasma)*. In older cattle, direct spread from a perisynovitis is the most common cause, and the distal interphalangeal joint is most often involved.

38.5.2 Pathogenesis

Articular blood supply is provided through a main arteriole that branches to the synovial membrane and epiphysis. Blood supply to the metaphysis is provided by the nutrient artery, but in young foals, transphyseal vessels exists that connect the metaphyseal and epiphyseal blood supply.[52] Experimental intravenous (IV) injection of bacteria results in rapid inoculation of articular and periarticular capillaries. Five types of hematogenous articular infection have been described: *type S* (synovial), where a septic arthritis results from inoculation of the synovial membrane; *type E* (epiphysis), where subchondral bone infection is present (Fig. 38-16); *type P* (physis), where infection of the physis occurs on the metaphyseal side of the growth plate (Fig. 38-17); *type T,* observed in premature foals, with infection of the small tarsal or carpal bones (Fig. 38-18); and *type I,* where joint invasion occurs after a periarticular soft tissue abscess (Fig. 38-19).[53] In young foals, functional transphyseal vessels allow communication of the metaphysis and epiphysis, such that bacteria localize preferentially in the synovial membrane and subchondral bone. Thus, young foals predominantly have infectious arthritis types S and E. Closure of transphyseal vessels occurs after about 7 to 10 days of age, such

that localization of infection to the metaphyseal vessel loops occurs in older foals.[52] Although bone inoculation can occur simultaneously with synovial inoculation in young foals, determination of bone involvement can be delayed until radiographs identify the lesions. In foals the hock, carpus, and stifle are frequently involved in hematogenous joint infection, but it is important to remember that any joints, including those of the vertebral column, can be affected. In young foals, *Actinobacillus equuli, Salmonella* species, *Escherichia coli,* and other Enterobacteriaceae are often involved; in older foals, *Streptococcus* species and *Rhodococcus equi* are common isolates. In foals with type P (physeal) involvement, *Salmonella* and *Rhodococcus* species are typically involved.

Fig. 38-16 Radiograph of a foal with type E septic arthritis showing involvement of the distal femoral epiphysis *(arrow)*.

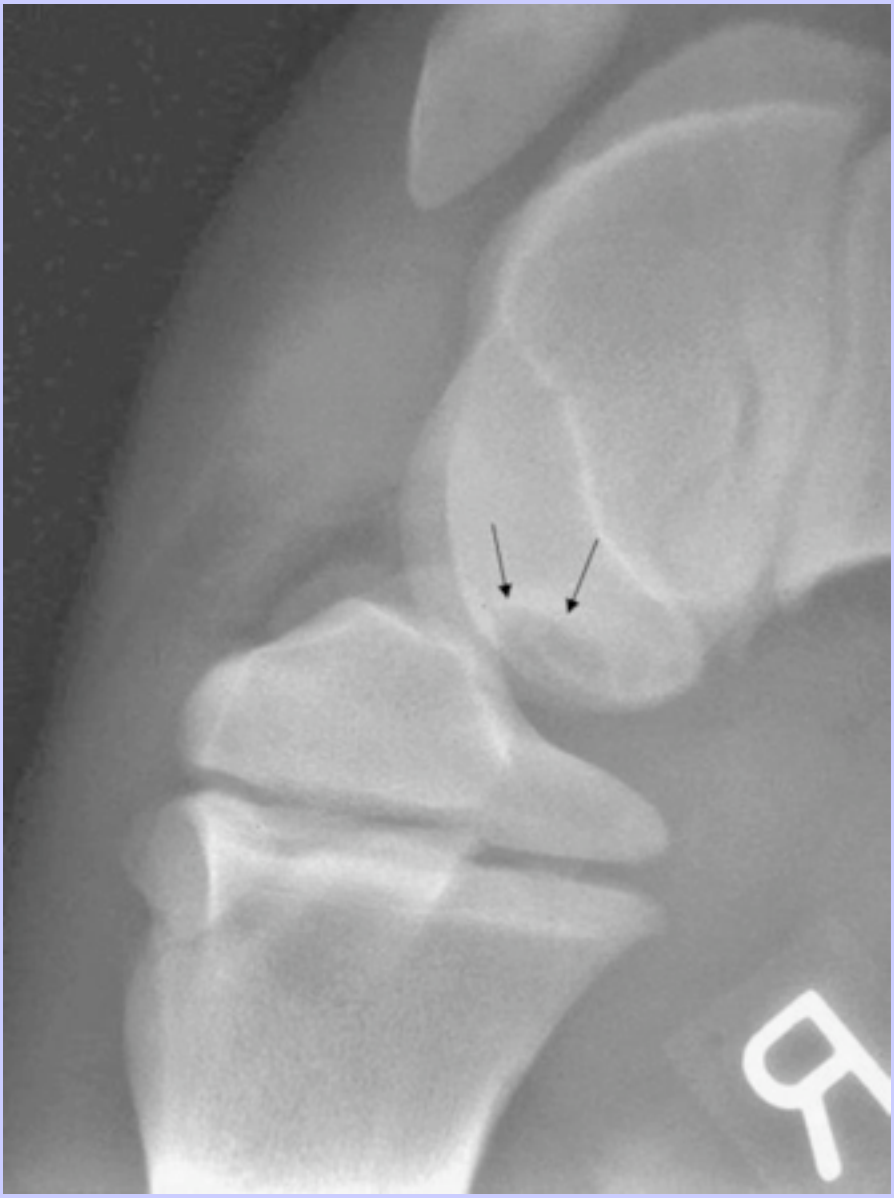

Fig. 38-17 Radiograph of a foal with type P septic arthritis showing involvement of the distal metacarpal physis *(arrows)*.

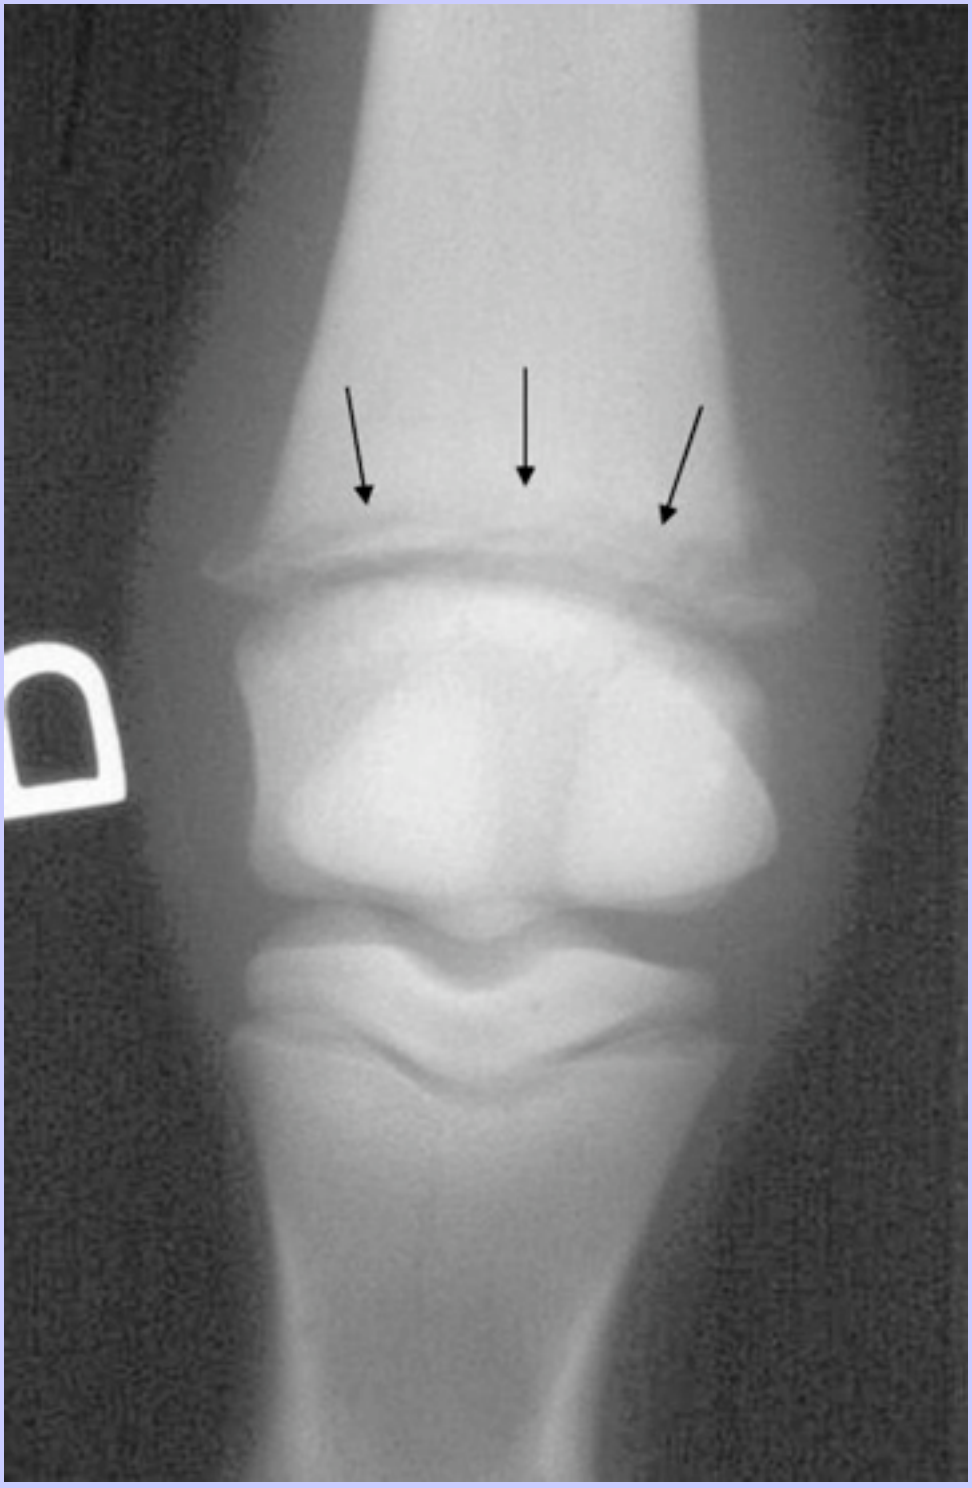

In adults, inoculation of the joint from an articular wound is the most common cause of joint sepsis. The establishment of infection will depend on size of the inoculum, pathogenicity of the bacteria, and duration before treatment. In one study, 53% of horses examined within 24 hours of an open joint wound developed septic arthritis, versus 92% of horses examined within 2 to 7 days of injury and 100% of horses examined after 7 days.[54] Joints of the lower limb (fetlock, coffin joint) are often involved in open joint injuries because of the poor tissue coverage in those areas.[48,55] Organisms frequently encountered in open joint wounds include Enterobacteriaceae, streptococci, and staphylococci.[48,55] These injuries are also likely to have multiple bacterial infections. Wounds near the hoof are more likely to have anaerobic infection, and *Clostridium* is the most common isolate. Fungal organisms are a rare cause of septic arthritis in horses but should be considered if isolated in pure culture more than once.[56]

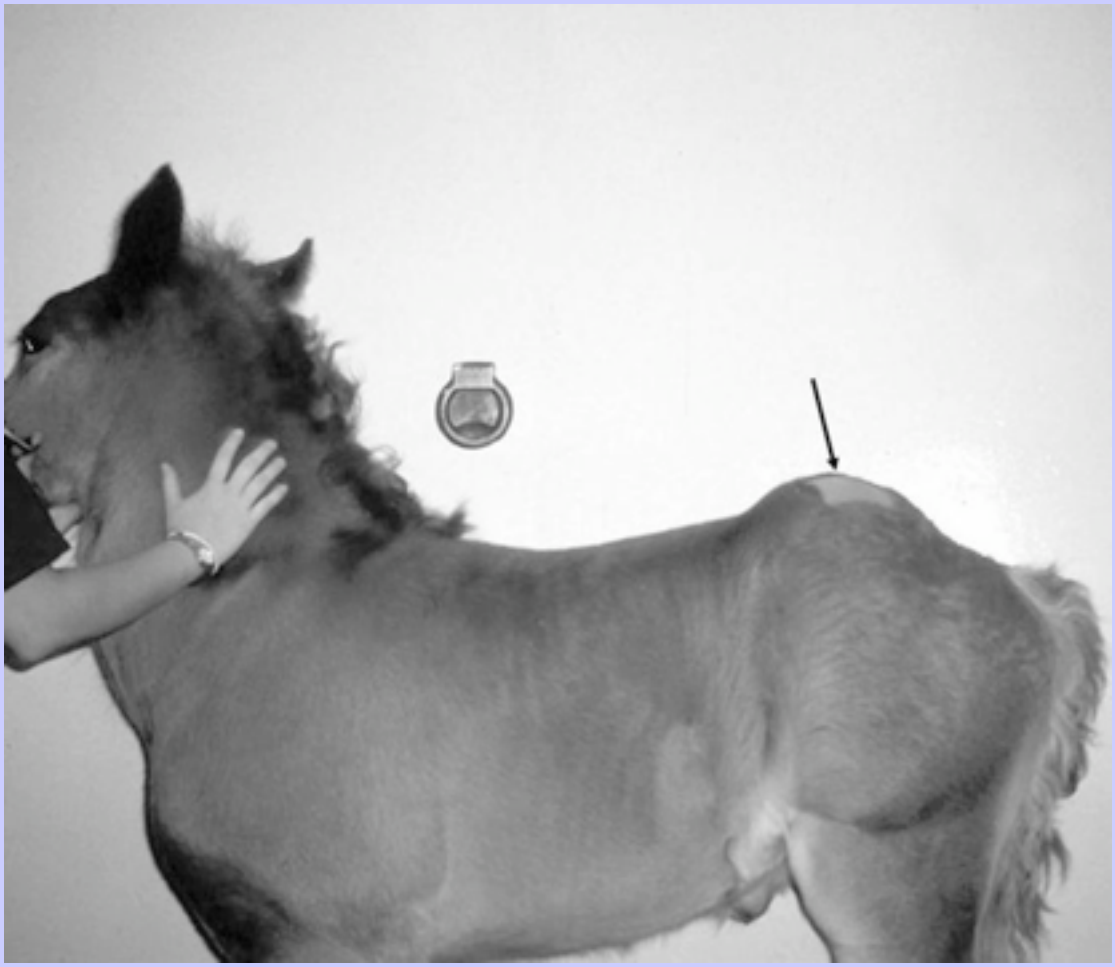
1201

Fig. 38-18 Radiograph of the tarsus of a premature foal with type T septic arthritis showing involvement of the distal tarsal bones *(arrows)*.

Fig. 38-19 Foal with type I septic arthritis where a soft tissue abscess *(arrow)* dissected down into the coxofemoral joint.



Iatrogenic joint injection is the second most common cause of septic arthritis in adults, followed by postoperative infection. The tarsus is the joint most often involved in septic arthritis after joint injection, whereas the carpus is the most common joint involved after surgery.[47,48] Staphylococci, particularly *Staphylococcus aureus,* are the most common organism isolated after iatrogenic joint injections or surgery. When *S. aureus* is isolated from a joint infection, care should be taken to identify further the possibility of methicillin resistance.[57,58] The risk of septic arthritis after arthroscopic surgery is low, 8 of 627 joints (1.3%) in one study.[59] Interestingly in these horses, clinical signs did not develop until several days after discharge.

In adult cattle, common pathogens involved in septic arthritis include *Mycoplasma bovigenitalium, Mycoplasma mycoides, Brucella* species, and *Arcanobacterium (Actinomyces) pyogenes,* which is most often involved.[60] In sheep, goats, and calves, *Chlamydia psittaci* polyarthritis can occur as an endemic or epidemic disease and may be accompanied by keratoconjunctivitis.[61,62] In lambs, *Erysipelothrix rhusiopathiae* is also a

cause of polyarthritis, gaining systemic entrance through the stump of docked tails or castration site. Improving hygiene during these procedures helps prevent the disease.[61]

38.5.3 Diagnosis

Septic arthritis, osteomyelitis, or physitis should be ruled out in any lame foal. Foals with septicemia are at high risk of developing septic arthritis, which generally is noted clinically hours to days after the initial signs of septicemia. Although owners often complain of external trauma, septic arthritis is the most common cause of lameness in foals. In young foals with types S and E arthritis, inoculation of the synovial membrane is the first event, which the astute clinician can identify as periarticular edema. Joint effusion rapidly follows. Involvement of multiple joints is common, and identification of all affected joints is essential for successful management. Because effusion of the shoulder, elbow, or hip joints is more difficult to detect by palpation, arthrocentesis of these joints should be performed in foals with an unidentified lameness. In the stifle, femoropatellar joint involvement results in marked effusion; however, femorotibial joint effusion is usually more difficult to discern. Because of the usual communication between the femoropatellar and the medial femorotibial joint, both are usually involved concurrently. Lateral femorotibial infection is more subtle to identify and can occur separately. Distention of the long extensor pouch is often present in lateral femorotibial infection and suggests involvement of that joint. In foals older than 7 days, physeal infection may be observed. With physeal infection, presence of concurrent synovial effusion depends on the intraarticular or extraarticular localization of the growth plate. For example, distal metacarpal physeal infection results in periphyseal edema, initially without joint effusion. The infection can break through the skin, rather than involving the joint. In foals with septic arthritis, the CBC is consistent with an inflammatory response and includes a neutrophilic leukocytosis and hyperfibrinogenemia.

1201

Adult horses usually show minimal changes on the CBC and little change in systemic signs; therefore the development or increasing lameness after a wound, joint injection, or surgery indicates the need for further examination. Because of their potent antiinflammatory properties, corticosteroids may delay the onset of clinical signs of septic arthritis after joint injection. In one study of experimentally induced septic arthritis, changes in synovial fluid were present before the onset of clinical signs, and clinical signs of lameness were delayed for 3 days in these horses.[63]

1202

Table 38-1 Characteristics of Synovial Fluid According to Condition in Large Animal

Characteristic	Normal	Septic	Degenerative Joint Disease	Inflammatory*
Color	Clear	Yellow/green, serosanguineous	Yellow	Yellow to iridescent
Clarity	Transparent	Turbid	Transparent	Translucent
Fluid volume	Low	Increased†	Low	Increased
Viscosity	High	Low	Variable	Low (usually)
WBCs/μL	<500	30,000	<5000	2000-10,000
PMNs (%)	<25	75	25	75
Total protein (g/dL)	<1	2.5	<1	1
Glucose	Equal to blood	<25 mg/dL	Equal to blood	25 to 50 mg/dL lower than blood
Gram or other stain	No bacteria seen	Bacteria may be seen	No bacteria seen	No bacteria seen

WBCs, White blood cells; *PMNs,* polymorphonuclear leukocyte neutrophils.

* May include low-grade sepsis in which bacteria are not found.

† Unless there is an open joint injury, in which fluid may be difficult too obtain.

Arthrocentesis is the mainstay of diagnosis of septic arthritis.[63] Table 38-1 lists the characteristics of synovial fluid according to conditions in large animals. A high protein concentration (>2.5 g/dL) and high white blood cell (WBC, leukocyte) count are observed. Classic counts diagnostic for septic arthritis in foals exceed 30,000 cells/μL, with greater than 90% neutrophils; however, cell counts greater than 10,000/μL may indicate early infection. Neutrophils are not always degenerate. Gram stain is a useful diagnostic tool because it may identify the etiologic agent in up to 25% of cases in which culture results are negative.[64] In foals with a separate physeal infection, where the physis is extraarticular, sympathetic joint inflammation and effusion can occur.[65] This manifests as a moderate increase in WBC count, with less than 90% neutrophils. The presence of such cytologic findings should alert the clinician and practitioner to the presence of physeal sepsis.

In adult horses with a wound localized near a synovial structure, it is crucial to identify as early as possible whether there is synovial involvement. The most convincing evidence is demonstration of synovial communication with a wound by injecting a sterile solution in the synovial structure and observing fluid exiting from the wound. For this purpose, a site remote from the wound and covered with normal skin should be prepared aseptically, and depending on the structure involved, 20 to 200 mL of a sterile solution (e.g., saline, balanced electrolyte) is injected, after collection of synovial fluid samples using aseptic technique.[66] If synovial involvement is detected, therapy is immediately instituted.

Radiographs of all affected joints are essential. The presence of osteomyelitis may affect prognosis and dictate prolonged antibiotic therapy. Radiographs should be repeated weekly until resolution of clinical signs, or any

time there is deterioration in the clinical condition. Radiographs are also indicated whenever a change in therapy is planned (e.g., from IV to oral antibiotics).

Nuclear scintigraphy has been used to diagnose infectious foci in odd localizations in foals. For example, vertebral and atlantooccipital involvements have been diagnosed using this imaging modality. It must be remembered that local bone infarcts, which are often present in osteomyelitis, will result in areas of decreased rather than increased uptake. Scintigraphy using technetium-99 m ($^{99\,m}$Tc)–labeled WBCs or ciprofloxacin labels has potential uses in foals with multiple-limb involvement and warrants further investigation as an imaging modality for septic arthritis.[67] Newer imaging capabilities (e.g., MRI, CT) may evolve as diagnostic modalities in septic arthritis (Fig. 38-20).

Identification of the organism should be attempted in all cases of septic arthritis. Gram stains, culture of synovial fluid in blood culture bottles, and culture of synovial biopsies have been suggested to increase the likelihood of identification of the organism. In general, the positive culture rate from synovial fluid samples is approximately 50%, and synovial biopsy culture has a low yield to increase this figure.[64] Appropriate culture techniques should be used for organisms such as *Chlamydia* or *Mycoplasma* species, and special stains may be required. In foals, because bacteremia or septicemia precedes the local signs, blood cultures should be obtained. In addition, any other local sites of infection should be cultured. In cases of septic physitis, needle aspiration of the affected site under radiographic or fluoroscopic guidance can be performed. In the future, other techniques for early identification of synovial sepsis may become available.[68]

1202

38.5.4 Treatment

Septic arthritis is an emergency. Immediate assessment followed by institution of treatment should be done as soon as possible after problem identification. Treatment of septic arthritis includes systemic broad-spectrum antibiotics, local joint lavage and debridement, and local antibiotics. Systemic antibiotics are best administered intravenously to ensure adequate tissue concentrations. Most often the combination of a β-lactam and an aminoglycoside or fluoroquinolone is used in adults; a β-lactam and aminoglycoside combination is most often used in foals because fluoroquinolones may have detrimental effects on articular cartilage in young animals. In open joint injuries, particularly if an anaerobic organism is suspected, metronidazole may be added to the antibiotic regimen. Gram-positive organisms can be isolated from blood cultures in up to 33% of foals with sepsis, so gram-positive coverage is also important.[69] In foals with physeal involvement, Gram stain and culture of a physeal aspirate are helpful to identify the causative agent. The most common organisms isolated from septic physitis are *Salmonella* species and *Rhodococcus equi*. If *R. equi* is identified, appropriate therapy with erythromycin, azithromycin, or clarithromycin and rifampin should be instituted, keeping in mind that resistance to rifampin and erythromycin has been reported; therefore, obtaining susceptibility patterns may be warranted.[70] In general, the presence of osteomyelitis may warrant an antibiotic combination that reaches effective bone levels; rifampin with another antibiotic is often used. Rifampin should not be used as the sole antimicrobial because resistance is acquired rapidly with this antibiotic. Other antibiotics that reach effective bone concentrations include tetracyclines, chloramphenicol, fluoroquinolones, and cephalosporins. If cephalosporins are chosen, third-generation agents (e.g., ceftiofur, cefotaxime, ceftriaxone, ceftazidime) are preferred because they are more effective against gram-negative bacteria. In foals, fluoroquinolones should be reserved for organisms that are only susceptible to this class of drugs because evidence shows cartilage lesions developing in immature animals with their use.[71,72]

Local lavage of the joint or synovial structure is an important component of therapy; removal of debris, fibrin, and inflammatory mediators helps minimize damage and eliminate the organism. In foals, joint lavage can be performed under heavy sedation or short-term general anesthesia. In adults, sedation and a regional block can be used or short-term general anesthesia. Joint lavage can be performed using through-and-through needle technique; use of a pressure bag or a pump will facilitate efficient lavage of several liters of fluids through the joint. This technique may be sufficient in joints where the diagnosis was made early, where the infection is not severe, and in simple joints (fetlock, carpus). If there is poor response to treatment after one or two sequential joint lavages, arthrotomies should be performed without hesitation. Often, fibrin accumulation in the affected joint precludes effective lavage and allows sequestration of bacteria. Once arthrotomies have been performed, the affected joint will need to be covered with a sterile bandage. During subsequent lavages, a teat cannula inserted in the arthrotomies may be used to lavage the joint. The arthrotomies are left to heal by second intention; the joint will need to remain bandaged until the arthrotomies are closed. Occasionally, delayed closure of the arthrotomies is necessary, particularly in arthrotomies localized over high-motion joints. In joints with multiple compartments (stifle, hock), in severe infection or osteomyelitis, in cases of longer duration, or in animals with poor response to joint lavage, arthroscopic debridement is indicated.[73] Arthroscopy has several advantages over simple needle lavage. It allows thorough debridement, removal of fibrin, and lavage of all compartments, as well as evaluation and debridement of cartilage and underlying bone lesions. In addition, arthroscopy may have prognostic value when radiographic lesions are equivocal. The arthroscopic portals can be left open for drainage and subsequent lavage but must be kept under a sterile bandage.

Intraarticular antibiotics are advocated for the management of septic arthritis. Delivery of local antibiotics to the affected joint can be achieved by intraarticular injection, regional IV or intraosseous (IO) perfusion, continuous

antibiotic delivery, or implantation of antibiotic-impregnated, biocompatible materials. Aminoglycosides (gentamicin, amikacin) and ceftiofur have been shown to maintain levels above the minimum inhibitory concentration (MIC) for 24 hours after a single intraarticular injection.[74,75] Other third-generation cephalosporins are also routinely used in the treatment of joint sepsis, at least until the susceptibility patterns are obtained. Antibiotic-impregnated polymethylmethacrylate (PMMA) beads can also be used, although direct implantation into a joint can result in cartilage damage.[76–78] PMMA implants are fabricated by mixing the desired antibiotic with the powder before adding the polymerizer. Antibiotics evaluated for inclusion in PMMA include gentamicin, metronidazole, vancomycin, ceftiofur, cefazolin, and amikacin.[79–87] Tetracyclines do not elute from PMMA and should not be used. Antibiotic combinations have also been used; metronidazole and gentamicin elute well from PMMA, but the combination of cefazolin and gentamicin is not recommended.[85,86] The implant is then molded into beads and strung on nonabsorbable suture material. The implant is placed into the affected joint or bone, and elution usually persists for approximately 7 days, with peak levels in the first 24 to 48 hours depending on the antibiotic used; the implant is then removed and may be replaced. Antibiotic-impregnated implants, such as gentamicin-impregnated collagen sponges,* have been evaluated experimentally and are commercially available in Europe.[88–90] Garamycin sponges consist of highly purified cattle collagen; the gentamicin molecules are embedded within the pores of the collagen. No stabilizing agents or foreign substances are added. A 50 × 50-mm sponge contains 32.5 mg of gentamicin base and 70 mg of collagen. The main advantage of these implants is that a separate procedure for their removal is not needed.

Regional intravenous perfusion (RIP) or intraosseous perfusion (ROP) are also advocated for the treatment of septic arthritis complicated with osteomyelitis.[91,92] The techniques are performed by first placing a tourniquet around the limb proximal to the location of the joint and/or bone involved. Regional perfusion cannot be performed for joints above the carpal/tarsal region because of the inability to place a tourniquet in those locations. After tourniquet placement, a regional vein is catheterized using a 23-gauge butterfly catheter for RIP; an IO screw is inserted for ROP.† The antibiotic is subsequently injected and the tourniquet left in place for 30 to 45 minutes. Antibiotics, particularly aminoglycosides and enrofloxacin, should be diluted in 20 to 40 mL of saline to avoid phlebitis at the injection site.

Continuous infusion of antibiotics can also be accomplished by placing a small catheter into the joint and attaching it to an infusion system‡ (pump syringe, balloon infuser).[93] In foals it is difficult to maintain these catheters in place, and considering the concentration of antibiotics achieved after intermittent intraarticular injection or regional perfusion, the aggravation of trying to make the system work is probably not warranted.

1203

1204

With extensive physeal lesions in foals, curettage, autologous bone grafting, and external coaptation may be required.[94,95] The addition of tricalcium phosphate granules or bioresorbable paste may be considered.[96] Angular limb deformities may result from growth disturbances or collapse of the physis on the affected side. In adults with septic arthritis and osteomyelitis, curettage of the bone lesion followed by bone grafting and external coaptation may also be indicated.[97] Adjunctive therapies that may help alleviate inflammation include sodium hyaluronate, polysulfated GAGs, and dimethyl sulfoxide (DMSO). Sodium hyaluronate and polysulfated GAGs can be used systemically or locally, but local use should be reserved for when infection is under control because these agents decrease joint defense mechanisms.[51,98] Although DMSO has significant antiinflammatory properties in joints, it should be used with caution because of its negative effects on cartilage metabolism.[99]

In addition to specific therapies, management of pain, stress, and other metabolic disturbances are indicated. Pain can be managed by judicious use of NSAIDs, using the smallest dose that will keep the animal

comfortable. If a foal continues to show severe pain despite appropriate treatment, it is important to ensure that other joints in the limb are not involved. Other pain management modalities, such as opiates, fentanyl patches, and epidural analgesia, can be attempted. It is important to remember that in foals, continued pain in one limb may result in development of a varus deformity in the contralateral weight-bearing limb, because of the tripod stance that these foals acquire to maintain the weight-bearing limb under the center of gravity. Application of a lateral extension to the contralateral foot may help increase the weight-bearing surface and prevent the development of this complication. Continued pain is a negative prognostic indicator in the affected foal. In adults, continued pain in one limb may result in the development of contralateral limb laminitis.[100] When continued pain in the treated limb is a problem, preventive measures (e.g., hoof support, therapeutic shoeing) should be undertaken.

The use of antiulcer agents is indicated in foals and adult horses that are in pain, stressed, and receiving high doses of NSAIDs. Omeprazole is currently the only medication that has been shown significantly to prevent formation of gastric ulcers and promote healing of existing ulcers in adult horses. Although evidence for its efficacy in preventing and treating NSAID-induced ulcers is lacking, omeprazole is still indicated when NSAIDs are used in stressed animals.

In cattle, facilitated ankylosis is a reasonable alternative when the disease is too advanced, and it is a particularly good option for involvement of the distal interphalangeal joint. Articulations of the distal limb in general are well suited to facilitated ankylosis. In brief, the involved joint is opened and debrided of all debris, all infected tissue is curetted and removed, and a cast is applied and maintained until ankylosis is achieved.[101] Alternatively, the digit may be amputated, although a reduced production life should be expected.[102]

38.5.5 Prognosis

Despite the relatively high prevalence of septic arthritis or osteomyelitis in foals, few studies have examined long-term outcome in affected foals. Furthermore, treatment is often limited by economic considerations, and therefore the true long-term outcome of treatment is not known. Prognosis for septic arthritis should always be guarded. Factors that will influence prognosis are systemic condition of the foal, number of joints involved, localization of joint involvement, severity of the infection, early versus delayed identification and institution of treatment, presence of osteomyelitis, and virulence of the organisms. In one study, 73/93 (78%) of foals survived to discharge, but only a third reached racing performance.[103] Isolation of *Salmonella* species and presence of multisystem diseases were negatively associated with survival and ability to race. In another study, 58/69 (84%) of foals survived to discharge, although signs were present for less than 24 hours in 74% of foals, only five foals had more than one joint involved, and only one foal had osteomyelitis.[104] This population of foals therefore appeared less severely affected. Of the affected foals, only 40.5% started in one race, and of the affected foals that were discharged, only 48.3% raced versus 66.2% in the control (sibling) group. This study concluded that even if foals are successfully discharged from the hospital, they are significantly less likely to start in at least one race than their siblings. Furthermore, these foals took significantly longer to appear on the track than their siblings.

In adults with open joint injuries, the prognosis can be favorable if the joint is contaminated but not yet infected, and if aggressive treatment is immediately started. However, with established infection, the prognosis

should always be guarded. In one study of horses with open joint injury, 53% of those examined within 24 hours developed septic arthritis, and overall survival was 65%. In horses presented within 2 to 7 days of injury, septic arthritis developed in 92%, and survival was 38.5%; in horses examined more then 7 days after injury, septic arthritis developed in all, and survival was 50%.[54] In one study of 101 horses with heel bulb lacerations, those with involvement of synovial structures had worse outcomes then those that did not; 5 of 17 horses with synovial involvement were euthanized.[55] Horses with contaminated or infected synovial structures treated by arthroscopic debridement appeared to have a better long-term outcome, with 106 of 118 (90%) surviving and 96 (81%) returning to previous use.[55] In a study of horses with septic tenosynovitis, 40 of 51 horses (78%) were discharged, and 37 of 40 (73%) survived long term, with 21 (57%) returning to intended use.[105] Surgical technique did not influence outcome in this study. Owners should be informed of the prognosis and high cost of treatment of infected synovial structures.

In cattle the prognosis for septic arthritis is generally better than in horses, probably because of the lack of expectation for athletic use. The prognosis depends on time of presentation, degree of bone involvement, and degree of extracapsular ankylosis. In two studies the success rate was reported as 72% and 85%; cattle with septic tarsi had a worse prognosis.[105a,105b] In another study, arthroscopic lavage and implantation of gentamicin-impregnated collagen sponges resulted in recovery in 12 of 14 cattle.[106] After arthrodesis of the distal interphalangeal joint, 85% success was reported.[102] For carpal arthrodesis, 87% success was reported if no carpal bone was removed, 72% success if one row of carpal bones was removed, and 35% if both carpal rows were removed. Tarsal arthrodesis has a reported success rate of 87% in cattle.[102]

38.6 *MYCOPLASMA MYCOIDES* POLYARTHRITIS OF GOATS

NANCY EAST

38.6.1 Definition and Etiology

Mycoplasma mycoides subspecies (ssp.) *mycoides* is a pathogenic mycoplasma that causes a variety of clinical syndromes in goats. Although the organism was formerly considered exotic to the United States, several large herd outbreaks have been described.[107,108] In most outbreaks the predominant clinical signs are polyarthritis and pneumonia in goat kids, occurring concurrently with mastitis in does. Abortions also may occur in pregnant does. Overwhelming generalized infection can occur in kids or adults, resulting in death.

1204

1205

38.6.2 Clinical Signs and Differential Diagnoses

Affected kids are from a few days of age to weaning age and have multiple warm swollen joints, elevated body temperatures of 40.8° C to 41.5° C (105.4° F to 106.7° F), pneumonia, and weight loss. They may have conjunctivitis. Many kids are unable to arise or reluctant to move. The acute febrile phase lasts 1 to 3 days, after which polyarthritic kids will be bright and alert and continue to eat. In addition, a few very young kids may exhibit central nervous system (CNS) signs (opisthotonos) or sudden death. Failure to respond to conventional antibiotic treatment or rapid relapse after treatment also characterizes outbreaks. Acute mastitis caused by *M. mycoides* ssp. *mycoides* is characterized initially as an agalactia with a firm, hot gland(s); the milk is brownish and watery with sandy clots. The affected doe is febrile, depressed, and anorexic; has diarrhea; may abort; and may have swollen joints or pneumonia. Some does develop a toxic shock—like syndrome and die rapidly, whereas others make an apparent clinical recovery with variable amounts of udder fibrosis and atrophy

remaining. The milk becomes normal in appearance, but intermittent chronic shedding of *M. mycoides* ssp. *mycoides* may occur.

Differential diagnosis in kids includes septic arthritis caused by bacteria, chlamydial polyarthritis, or white muscle disease, whereas in adult does the mastitis must be differentiated from that caused by *Mycoplasma putrefaciens* and other bacteria. Other *Mycoplasma* species, particularly *M. putrefaciens,* occasionally cause polyarthritis in goat kids.

38.6.3 Clinical Pathology and Laboratory Aids

Most affected kids have an increased WBC count (>13,000 WBCs/mm^3 with neutrophilia >7200 cells/mm^3, monocytosis >530 cells/mm^3) and plasma fibrinogen (>400 mg/dL). Peracutely affected kids and does have a CBC typical of toxic shock, with neutropenia and a degenerative left shift. The joint fluid is increased in volume and contains large fibrin clots with increased numbers of neutrophils and lymphocytes. The organism is usually cultured on mycoplasma media from the most applicable affected site (joint fluid, milk, tracheal wash).

38.6.4 Pathophysiology

M. mycoides ssp. *mycoides* infection leads to mycoplasmemia and multiple organ involvement of varying degrees, with pyrexia, fibrinopurulent polyarthritis, pneumonia, pleuritis, pericarditis, peritonitis, mastitis, abortion, and encephalitis the most common clinical expressions of infection. Recovery is accompanied by the conversion to carrier status in many animals with intermittent shedding of *M. mycoides* ssp. *mycoides* in milk and in ocular and nasal secretions. Pathogenic mycoplasmas are thought to produce toxins, but little is known of the pathogenesis of mycoplasmal diseases.

38.6.5 Epidemiology

M. mycoides ssp. *mycoides* is usually a milk-borne infection that enters herds through inapparent carriers (usually adult milking does). The organism is an obligate intracellular parasite and survives poorly in the environment. It is easily transmitted to other does during normal milking operations and to young stock by ingestion. One milliliter of infected milk contains enough organisms (10^6) to cause polyarthritis in kids.[109] In reported outbreaks the morbidity is high (60% to 90%), and the mortality is 15% to 91%. The morbidity and mortality are highest in young animals. Transmission by contact occurs in conjunction with high-density stocking rates. Environmental and other stressors (transport, kidding, kid processing, changes in herd grouping) induce shedding in chronic carrier animals and may facilitate herd outbreaks. The goat ear mite (genus *Psoroptes*) may play a role in maintaining a reservoir for *M. mycoides* ssp. *mycoides*.[110] Numerous isolations have been made from the external ear canals of clinically normal goats infected with mites.

38.6.6 Necropsy Findings

Gross necropsy findings may include fibrinopurulent polyarthritis, with erosions of articular surfaces, fibrinous pleuritis, fibrinous pericarditis, pneumonia, mastitis, peritonitis, and conjunctivitis. Subcutaneous edema often extends into soft tissues above and below the joint. In addition, meningoencephalitis may be appreciated on gross examination. Histologically, affected tissues exhibit neutrophilic infiltration with perivascular infiltration of plasma cells and lymphocytes.[107,108]

38.6.7 Treatment and Prognosis

There is no effective treatment for *M. mycoides* ssp. *mycoides*. Treatment with antibiotics may result in complete or transient remission followed by relapse. Naturally recovered animals are considered to be carriers, although the number of exposed-recovered kids that remain carriers is not well understood. Treatment with tylosin (10 to 50 mg/kg three times daily) may result in apparent clinical improvement, but the associated risk of producing carrier animals weighs against treatment. Newly developed antibiotics may make successful treatment possible in the future.

38.6.8 Prevention and Control

M. mycoides ssp. *mycoides* can be prevented from entering goat dairies by isolating and performing milk cultures on new herd additions. Milk cultures should be performed at purchase and 2 and 4 weeks later, before the doe is declared free of *M. mycoides* ssp. *mycoides*. If the doe is dry at purchase, isolation should be maintained until she is cultured at kidding and 2 and 4 weeks fresh. Herd outbreaks are controlled by feeding cow colostrum, cows' milk, or milk replacer to kids and by performing milk cultures on individual does. Initially, each doe should have a composite milk sample cultured for mycoplasma.

Does with positive cultures are culled to slaughter or are housed together and milked last until they can be sold to slaughter. At weekly intervals after the milk tank has been emptied, a culture is taken after each string is milked, and the identity of each doe that contributed to the can or tank string sample is recorded. If a positive culture occurs in a string, individual cultures must be performed on that string to identify the doe(s) shedding *M. mycoides* ssp. *mycoides*. After 1 to 2 months of weekly cultures, monthly string cultures are adequate, combined with individual cultures for all does kidding. After 6 to 8 months, monthly bulk tank samples and fresh doe samples are monitored for 1 more year. The majority of infected lactating does are identified in the first 4 weeks of milk culturing. Some does infected with *M. mycoides* spp. *mycoides* may remain undetected for years even with intensive surveillance, thereby leading to sporadic disease. All kids that were being fed milk on the dairy during the outbreak should be sold for meat if they are in satisfactory condition, whereas clinically affected kids should be euthanized because, even with treatment, they may become carriers.

1205

1206

38.7 CAPRINE ARTHRITIS-ENCEPHALITIS VIRUS

KEVIN E. WASHBURN

38.7.1 Definition and Etiology

Caprine arthritis-encephalitis virus (CAEV) is an RNA-enveloped lentivirus from the Retroviridae family that infects cells of the monocyte-macrophage lineage, with manifestations ranging from subclinical disease to severe encephalitis. Time from infection by the virus to clinical disease may vary from months to years. Infection with CAEV is lifelong, so efforts to eradicate and control its prevalence and incidence are paramount to maintaining successful goat herds. The economic impact of this disease in herds and the goat industry involves loss of productivity, death, and restrictions on the export of diary goats in the United States.

38.7.2 Clinical Signs

Clinically, only approximately 20% of CAEV-infected goats display signs of disease during their lifetime. Recognized forms of disease include a leukoencephalomyelitis, interstitial pneumonia, chronic mastitis, and debilitating polysynovitis-arthritis. *Leukoencephalomyelitis* is observed primarily in kids 2 to 6 months of age, although cases have been reported in adults.[111] This form of CAEV infection is characterized by an ascending paresis leading to paralysis, beginning in the hindlimbs and sometimes involving the forelimbs. These signs may or may not be accompanied by a mild interstitial pneumonia. Goat kids surprisingly may continue to be bright, alert, and appetent. The most severe manifestation of leukoencephalomyelitis is progressive paresis to paralysis to urinary retention and bloating. *Chronic interstitial pneumonia* with progressive weight loss and dyspnea is another recognized form of CAEV infection. Primary ruleouts for this form should include lung worms, pulmonary abscessation, and chronic bronchopneumonia. The mammary gland is a target organ for CAEV, resulting clinically in a firm udder with decreased milk production *(chronic mastitis)*. Although quantity of milk is reduced, grossly, there are no apparent abnormalities.

The most common form of CAEV infection is *polysynovitis-arthritis,* which can be recognized in goats as young as 6 months but more frequently is observed in mature goats. Lameness caused by this form is intermittent and insidious in onset; eventually, however, affected joints become painful and enlarged. Enlargement of the joints is most often caused by hyperplasia of the synovial tissues and their associated sheaths, rather than increased volume of joint fluid. The carpus is most frequently involved, but the stifle, coxofemoral, atlantooccipital, and hock joints are also potential locations. Affected goats have a stiff, stilted gait and progress to walking on their carpus or recumbency. Range of motion is greatly affected, which contributes to chronic contracture of the soft tissue. This polysynovitis-arthritis form of CAEV infection can be accompanied by chronic interstitial pneumonia and weight loss and typically is also associated with some form of mammary involvement.[111]

38.7.3 Diagnosis and Clinical Pathology

On suspicion of the polysynovitis-arthritis form of CAEV infection, arthrocentesis usually yields a brown to red-tinged fluid, with an increased cell count and decreased protein. Joint fluid cell counts in affected joints are dominated by mononuclear cells, which differs from the bacterial synovitis usually observed, consisting predominantly of neutrophils. This predominance of mononuclear cells is also seen in the cerebrospinal fluid (CSF) of goats affected with the leukoencephalomyelitis form. Radiographs may be a useful tool in the diagnosis of CAEV polysynovitis-arthritis in that early cases display soft tissue swelling dorsal to the carpus. Later, as the disease progresses, mineralization can be observed in the periarticular tissue, tendon sheaths, joint capsules, and ligaments. Roughened bone proximal and distal to the joint becomes apparent, along with a periosteal reaction.

The U.S. Department of Agriculture (USDA) recognizes agar gel immunodiffusion (AGID) using ovine progressive pneumonia virus antigen as the official test for CAEV. However, an enzyme-linked immunosorbent assay (ELISA) has been developed for detection of whole-virus, core, or envelope proteins. Both AGID and ELISA are considered reliable enough to be incorporated into prevention and control programs. The AGID test is reportedly more specific, but less sensitive, than the ELISA.[112] Detection of antigen in milk, tissue, and blood can be facilitated through polymerase chain reaction (PCR) techniques. A positive AGID or ELISA in adults is synonymous with lifelong viral infection. Generally, time from infection to seroconversion ranges from 4 to 16 weeks, although some infected goats shed virus for long periods without seroconversion.[113] Goat

kids may be transiently positive for the presence of antibodies during the first 8 to 16 weeks of life after consuming CAEV antibody—containing colostrum; however, because of the nonprotective nature of the maternal antibodies, such kids may seroconvert from true viral infection due to shedding of the virus from the infected dam.

38.7.4 Pathophysiology

The characteristic granulomatous inflammatory pathology produced in affected tissues is thought to be caused by immune complexes generated by the interaction of nonneutralizing antibodies produced by lymphocytes and associated virus-infected macrophages. Localization of such inflammatory lesions occurs where tissue-associated macrophages are found. Tissues of importance in CAEV localization include the synovium, mammary gland, and CNS; therefore the clinical manifestations of the disease are logical.

38.7.5 Epidemiology

Transmission involves the transfer of virus-laden cells from one animal to the next. Transfer of CAEV to neonates through colostrum and later milk is a highly efficient, natural mode of transmission.[114,115] Transmission has also been reported through direct contact; consequently, herds that do not practice segregation of seropositive animals have ongoing difficulty controlling and eradicating the disease.[114–117] Complete separation of kids from the dams immediately after parturition and during the periparturient period is necessary because even kids not allowed to nurse become infected. CAEV proviral DNA has been recently detected in the female caprine genital tract,[118] and experimental infection of goat embryos with CAEV has been reported.[119] Intramammary and in utero transmission also have been described.[117,120] All these means of acquiring CAEV are potential explanations for continued transmission in herds that practice segregation and sound colostrum and milk management.

Maedi-visna virus (MVV), also known as “ovine progressive pneumonia,” is another lentivirus that, together with CAEV, is often referred to as “small ruminant lentivirus” (SLV). Although sheep are most likely to display clinical signs of MVV and goats to have signs of CAEV, studies have shown that these viruses can be transmitted from sheep to goats, and vice versa.[121] Therefore, eradication programs aimed at eliminating SLV from herds and flocks should not allow contact between sheep and goats.

The last study examining the prevalence of antibody to CAEV in the United States found that 31% of all goats tested were seropositive and that 73% of herds had at least one seropositive member. Serum samples in this study were obtained from 28 states. The prevalence was highest in the western Pacific and northern plains regions, on family-owned farms, and increased with age. Prevalence in this study was lowest in the Angora breed.[122] 1206 1207

38.7.6 Necropsy Findings

Grossly, goats affected with the polysynovitis-arthritis form of CAEV have thickened, sometimes folded synovium consistent with synovial hyperplasia resulting from chronic inflammation. Microscopically, synovial hyperplasia is characterized by mononuclear infiltration of lymphocytes, plasma cells, and macrophages. Synovial spaces contain fibrin, whereas synovial villi and collagen are necrotic.[111]

No gross lesions are apparent in the CNS of goats affected with the leukoencephalomyelitis form of CAEV; microscopically, however, perivascular infiltration of lymphocytes, macrophages, and plasma cells are observed. Perivascular infiltration is often accompanied by malacia of the brain and spinal cord in addition to loss of myelin. Occasionally, degenerative lesions are seen in the gray matter.[123]

38.7.7 Treatment and Prognosis

Prognosis for CAEV infection varies because most goats do not show clinical disease; once signs begin, however, rapid deterioration ensues. Arthritis and accompanying weight loss are progressive, and there is no treatment. Kids or mature goats affected with the leukoencephalomyelitis form do not survive and should be euthanized for humane reasons. Reportedly, a genetically determined predisposition for development of the CAEV arthritis exists and can be identified through the use of DNA fingerprinting.[124]

38.7.8 Prevention and Control

Prevention and control are based on colostrum and milk management, although kids should also be prevented from any contact with the dam after parturition. Heat treatment of colostrum by holding it at 45° C (113° F) for 1 hour is effective in inactivating the virus.[117] Kids can then be fed pasteurized milk until weaning. Goats' milk from seronegative dams that is not pasteurized is a risky substitute for heat-treated milk because some seronegative goats shed virus for long periods before seroconversion occurs. Pooling of colostrum increases the prevalence of disease on goat dairies, so this practice should be restricted. Kids should be tested serologically at periodic intervals to detect and remove infected individuals. Seronegative goats should be isolated from seropositive ones by a minimum of 6 feet (1.8 m).[117] Sharing of feed and water troughs should not be allowed, nor should the use of common needles during routine vaccination or administration of medication. During breeding, seronegative does should not be housed with seropositive bucks; however, they can be hand-mated and quickly reisolated. New additions to the herd should be tested and isolated until seronegative status is confirmed before entry into the herd.

Despite diligent prevention and control programs based on elimination of colostrum and milk transmission, isolation of seronegative goats, and serologic monitoring, obstacles to a CAEV-free herd are often encountered. Detection of virus has been reported in properly treated colostrum.[114] Colostrum that is overheated denatures immunoglobulin, thereby preventing effective passive transfer of immunity, and colostrum not heated long enough or at sufficiently high temperature fails to inactivate the virus. Feeding overheated colostrum may also cause diarrhea in the kids.[125] Therefore, attention to times and temperatures during heat treatment of colostrum and pasteurization of milk is crucial for effective colostrum and milk management. Some farms routinely feed cow colostrum; however, neonatal isoerythrolysis has been reported in kids consuming cows' milk, and the lack of goat-specific immunoglobulin transfer is less than ideal.[125] Serologic monitoring can be complicated by shedding of the virus before seroconversion. All goats must therefore be tested at least twice yearly to ensure that new cases are detected and managed accordingly. Unfortunately, no vaccine is currently available for CAEV.

38.8 OSTEOARTHRITIS

MELINDA H. MacDONALD

38.8.1 Definition

The term osteoarthritis (OA) encompasses a large group of joint disorders that are characterized by progressive, permanent deterioration of the articular cartilage.[126–129] Cartilage damage is often accompanied by changes in the adjacent bone and soft tissue structures, including subchondral bone sclerosis, periarticular new bone formation, and synovial inflammation. Unfortunately, some confusion and debate surround the best term to use for this broad group of disorders. Osteoarthritis, degenerative joint disease (DJD), osteoarthrosis, and secondary joint disease have been used almost interchangeably in veterinary medicine.[126,127] However, *osteoarthritis* emphasizes the characteristic synovial inflammation detected in most patients, and this term is used here.

Interestingly, OA is one of the oldest documented orthopedic conditions. In fact, the fossilized remains of early dinosaurs suggest that OA predates the evolutionary development of mammals. Unfortunately, however, questions remain regarding the etiopathogenesis of OA, and this condition is still regularly diagnosed in most large animal species, including horses, cattle, and small ruminants. In goats, OA is frequently associated with CAEV (see previous discussion).[130,131] In pigs, OA is a common debilitating sequela of infectious arthritis or osteochondrosis.[132] Although not routinely diagnosed in sheep, OA has been reported to develop in individuals infected with ovine progressive pneumonia.[130] In contrast, joint disease is a common and expensive problem in the equine industry, and a wide variety of athletic injuries can progress to a common endpoint with stereotypic features of chronic OA.[126–128]

38.8.2 Etiology and Classification

Many factors, including athletic performance, repetitive trauma, and age, are thought to influence cartilage homeostasis and contribute to degenerative changes in the joint. Contrary to the traditional view of articular cartilage as a passive bystander subjected to overexertion and traumatic wear-and-tear damage, it is now recognized that both resident and infiltrating articular cells have a critical role in the development of OA. Cartilage degeneration is an active process ultimately resulting from the inability of resident cells to maintain a normal balance between matrix synthesis and degradation. This occurs when chondrocytes and synovial cells are exposed to various nonphysiologic stimuli, including trauma and inflammation. Once the balance is disrupted, proteoglycans within the hyalin cartilage matrix are depleted and reduced in size, while the collagen meshwork progressively deteriorates. These changes in turn alter the mechanical properties of articular cartilage. A variety of different joint problems can initiate an imbalance between the rates of cartilage degradation and repair and, if left untreated, will ultimately progress to a common endpoint of OA.

Although a number of initiating and predisposing conditions have been identified, it is generally thought that trauma, either a single severe injury or low-grade repetitive damage, is the most important basis for the development of OA in large animal species.[126–128] In many cases the traumatic damage is augmented by abnormal weight bearing, poor-quality cartilage, or congenital joint instability, such as that seen with hip dysplasia in calves. In addition, OA frequently develops in joints that have unresolved or untreated osteochondrosis, subchondral bone collapse, or septic arthritis. In all these cases, the link between the cause and the end result of OA is a series of complex biochemical and metabolic events that are not yet fully understood. Regardless of the inciting etiology, advanced OA is characterized by fibrillated and ulcerated cartilage, eburnation and sclerosis of the subchondral bone, hyperplasia of the synovial membrane, and development of periarticular osteophytes.

Several classification schemes have been proposed to group clinical OA conditions in both human and veterinary medicine. One useful classification developed for equine OA defines three main categories of disease based on predisposing causes and clinical findings.[131] The categories include OA associated with synovitis and capsulitis (type 1), OA secondary to other identified injuries or disorders (type 2), and incidental or nonprogressive articular cartilage erosion (type 3).[127] For example, type 2 OA would include the chronic degenerative changes typically associated with intraarticular fractures, septic arthritis, osteochondrosis, and traumatic cartilage or ligament injuries. All three categories are routinely identified in equine athletes, but this simple scheme can easily be applied to other large animal species as well. For example, cattle most often develop type 2 OA as a consequence of septic arthritis, cruciate rupture, osteochondrosis, or nutritional deficiencies.[132]

A second way of classifying OA is based on the possible deleterious effects of biomechanical forces on normal and abnormal joints.[128] According to this scheme, the first of two major causes of OA is the concentration of abnormal forces on a previously normal joint. For example, OA can develop when there is increased weight bearing on one limb to protect a painful contralateral limb. The second major cause is the concentration of normal forces on an abnormal articulation, such as the joint damage that occurs when normal weight-bearing forces are applied to cartilage previously exposed to infection.

38.8.3 Pathology and Pathogenesis

Despite the many pathways by which OA may develop, the resulting changes in the joint are essentially indistinguishable regardless of the initiating cause. By definition, this condition has a characteristic picture of cartilage damage with variable amounts of hypertrophic cartilage and bone remodeling. Pathologic features include different degrees of cartilage splitting and fragmentation, extending to complete erosion and loss of articular cartilage.[126–128] Typically, the rate of disease progression and severity of OA are related to the nature and severity of the primary insult, the animal's age at the time, the joint location, and the animal's type and level of activity.

The pathogenesis of these changes is only partially understood. Several explanations have been proposed for the failure of resident chondrocytes to maintain the extracellular matrix. Mechanical trauma to the joint surface could initiate matrix damage, and repetitive microtrauma could damage chondrocytes and physically disrupt the joint surface. Leukocytes in an inflamed joint release destructive enzymes, which can degrade the cartilage surface. Recent work has also demonstrated that various polypeptide mediators released in inflamed joints can stimulate chondrocytes to degrade their surrounding matrix. Regardless of the initiating factor, once the balance of chondrocyte-matrix turnover is shifted toward degradation, proteoglycans are rapidly depleted from the extracellular matrix, and collagen fibers are exposed to direct traumatic and enzymatic breakdown. Unfortunately, hyaline cartilage has no effective intrinsic repair mechanism.

Articular cartilage damage is accompanied by changes in the adjacent subchondral bone (e.g., sclerosis), joint capsule (e.g., synovial hyperplasia, thickening of fibrous joint capsule), and joint margin (e.g., osteophyte formation, enthesophyte formation at joint capsule and ligament insertions).[128] Subchondral bone sclerosis may develop from an abnormal distribution of forces under damaged articular cartilage, or it may actually precede the cartilage damage. It is now known that bone remodeling and subchondral bone sclerosis occur in response to repetitive cyclic compression during exercise and, in certain cases, could result in trauma to the overlying articular cartilage and predispose to the development of OA (e.g., third carpal bone disease in horses). Joint

margin changes occur as a result of progressive cartilage deterioration and subchondral remodeling (osteophytes) or joint instability (enthesophytes).

38.8.4 Clinical Signs

History and occupation are important for identifying animals at risk for developing OA. Typically, the first sign that an owner or caretaker recognizes in an affected animal is lameness or stiffness. Whereas the pain and dysfunction may develop insidiously, the owner will often report a sudden onset of clinical signs. Flexion and extension of an involved joint frequently exacerbates the lameness or elicits a pain response. Because articular cartilage is aneural, pain is thought to result from joint inflammation and secondary changes in adjacent tissues. Pain receptors are abundant in joint capsule, articular ligaments, and subchondral bone. Joint stiffness may be associated with guarding of a painful joint. Decreased range of motion with joint capsule inflammation is also common. Osteophytes and enthesophytes may be palpable in chronic cases of bone spavin and ringbone. A postural deformity may be evident if articular degeneration progresses to ankylosis. It is also important to remember that OA may exist in the absence of any clinical signs.

Gait abnormalities compatible with OA include shortened stride length, limb abduction, and dragging the toe. Increased lameness after sustained flexion of a single joint suggests that the joint is involved. Horses with OA often present early in the course of disease with a primary complaint of poor performance. These individuals can warm out of the lameness, or temporarily improve with rest, and are often difficult to diagnose. In contrast, food animals typically present in the advanced stages of OA. Rams and bulls may stand post-legged and appear weak in the rear when the hindlimbs are severely affected. In all species the severity of signs varies with the joint affected, stage of disease, amount of inflammation, cartilage degeneration, and periarticular changes.

38.8.5 Diagnosis

Regional nerve blocks and intraarticular anesthesia can be useful for determining the origin of lameness. Unfortunately, standard synovial fluid analysis typically shows only minimal, nonspecific changes. Although 1208
not useful for determining the severity of cartilage destruction, cytology is often useful for differentiating OA 1209
from other causes of synovial inflammation (e.g., septic arthritis). A variety of synovial fluid markers have been evaluated as possible diagnostic aids for evaluation of equine synovitis and joint disease (e.g., cytokines, eicosanoids, GAG concentrations, immune complexes, collagen type-specific antibodies and propeptides, cartilage wear fragment, free-radical oxidation products, polymerization of hyaluronate, chondroitin sulfate epitopes). Current detection techniques for cytokines and eicosanoids may prove useful diagnostically and prognostically.

After identification of an involved joint, radiographs are used to determine the severity and extent of disease. Articular cartilage is not visualized but may be indirectly assessed by evaluating joint space width. In contrast, the associated subchondral and periarticular bone reaction can be directly evaluated. Radiographic signs of OA develop gradually, affect opposing joint surfaces, and may include destructive as well as productive lesions. Changes typical of advanced OA include marginal osteophyte proliferation, periosteal new bone production at sites of joint capsule and ligamentous attachments (enthesophytes), narrowing or obliteration of the joint space, subchondral bone sclerosis, and occasionally, subchondral lysis. Early in the disease, no bony lesions may be detected, and clinical findings from the entire examination must be considered. Radiographic changes associated with OA must be differentiated from similar bone reactions caused by active infection, fractures, osteochondrosis, and invasive tumors. Infectious arthritis classically causes rapid, widespread osteochondral destruction. Minimally displaced fractures may mimic OA but are usually discrete, isolated lesions. Knowledge

of the characteristic site distribution and site-respective appearances of osteochondroses in each species is useful for differentiation from OA. The presence of OA in joints with osteochondrosis usually worsens the prognosis.

Scintigraphy is particularly valuable in early disease states when conventional diagnostic methods have not revealed bone or soft tissue changes. Increased scan activity is associated with soft tissue inflammation or increased bone remodeling, but alone it is not diagnostic for OA. Arthroscopy is the best method for gross evaluation of articular cartilage and is most useful when lameness has been localized to a specific joint but no bony changes are detected radiographically. This technique provides the added therapeutic benefit of simultaneous joint lavage. Although arthroscopy was initially promoted for diagnostic and therapeutic use in equine patients, these techniques are gaining popularity in food animal practice as well.[133]

38.8.6 Treatment

The choice and efficacy of treatment depend on the inciting cause of OA, stage of cartilage degradation, joint involved, and degree of active inflammation. In general the treatment of OA should be directed at eliminating any primary causes, reducing active joint inflammation, and treating articular cartilage loss or degeneration.[126,127,134] Early treatment of primary problems minimizes the extent of secondary joint damage. For example, fractures and osteochondritis dissecans can often be managed successfully with arthroscopic surgery; however, early intervention is essential to avoid the secondary changes of OA.

Many therapeutic options are designed to treat active soft tissue inflammation and prevent progression of articular cartilage damage. Rest is the simplest but often the most difficult recommendation to enforce, especially when dealing with elite performance horses. There are also valid concerns that complete rest may result in resorption of subchondral bone and predispose the horse to subsequent injury. Other treatments for soft tissue disturbances in the joint include physical therapy and controlled exercise, systemic NSAIDs (e.g., phenylbutazone, flunixin meglumine), joint lavage, and topical application of antiinflammatory products.

Numerous medications have been specifically designed and marketed for treating OA in human and veterinary patients. However, many of these products remain controversial in terms of their safety and efficacy in large animals. The most popular formulations include intraarticular corticosteroids, intraarticular and intramuscular polysulfated glycosaminoglycans (GAG), intraarticular and intravenous hyaluronan, and oral GAG supplements.

Intraarticular steroids are the most potent antiinflammatory agents available; historically, however, they have been associated with progressive cartilage damage.[134,135] Nevertheless, investigations critically evaluating the effects of corticosteroids in equine joints suggest that when administered at physiologic doses, these drugs may have beneficial protective effects.[134,135] Current recommendations emphasize the need for appropriate caution and encourage the use of low doses of steroids in conjunction with other antiinflammatory medications. Hyaluronan (sodium hyaluronate) is currently used both intravenously and intraarticularly to treat synovial inflammation and OA in the horse.[134,136] The intraarticular products vary in molecular weight and cost and include cross-linked hylans, which may prolong intraarticular retention. Clinical reports document the efficacy of hyaluronan for mild to moderate synovitis, and some research supports an inhibition of proteoglycan degradation and inhibition of synoviocyte release of various inflammatory mediators. Other studies failed to demonstrate beneficial effects in joints with significant articular cartilage damage or osteochondral fragmentation.

The intraarticular administration of polysulfated GAG has been reported to reduce progressive degenerative changes in articular cartilage, but is controversial in terms of its ability to augment the chondrocyte repair response.[134,137] Intramuscular use is advocated because intraarticular use has been associated with adverse reactions and potentiates the risk of iatrogenic joint infection.[134,137]

There is still great interest in the use of nutritional supplements to prevent and treat OA, with a proliferation of products promoted as beneficial to joint health and cartilage regeneration.[138] Among the most popular are the oral glucosamine sulfate and chondroitin sulfate preparations. However, oral absorption of chondroitin sulfates has not been documented in the horse, and although clinical reports suggest a beneficial effect from these supplements, additional controlled studies are needed to confirm these effects. Methylsulfonylmethane (MSM), a dietary derivative of DMSO, is also being used as a dietary supplement to control the inflammation associated with OA. Again, minimal documentation exists regarding its value in treating joint disease in large animals. Other compounds to treat OA include *S*-adenosyl-L-methionine and various vitamins known to provide antioxidant protection.

The most challenging aspect of OA management is treatment of existing articular cartilage degeneration and loss. Partial-thickness cartilage defects do not heal, and full-thickness defects heal with inferior fibrocartilaginous tissue. Some surgical techniques (e.g., curettage, subchondral bone drilling, microfracture) facilitate defect repair by enhancing fibrocartilage ingrowth from the underlying subchondral bone; however, fibrocartilage is biomechanically inferior to normal hyaline cartilage. Grafting cartilage defects with periosteum, perichondrium, and sternal cartilage has not been encouraging. More recent work focuses on transplantation resurfacing using chondrocyte grafts and growth factors to stimulate repair.[139]

1209

1210

38.8.7 Prognosis

Prognosis for animals with OA depends on the initiating factor(s), extent of the secondary disease, joint affected, and intended use of the animal. With early and aggressive treatment, many animals can return to soundness and athletic performance. In other cases, salvage in the form of surgical arthrodesis may provide the most favorable outcome.

38.9 SPRAINS, SUBLUXATIONS, AND LUXATIONS

WILL C. JORDAN

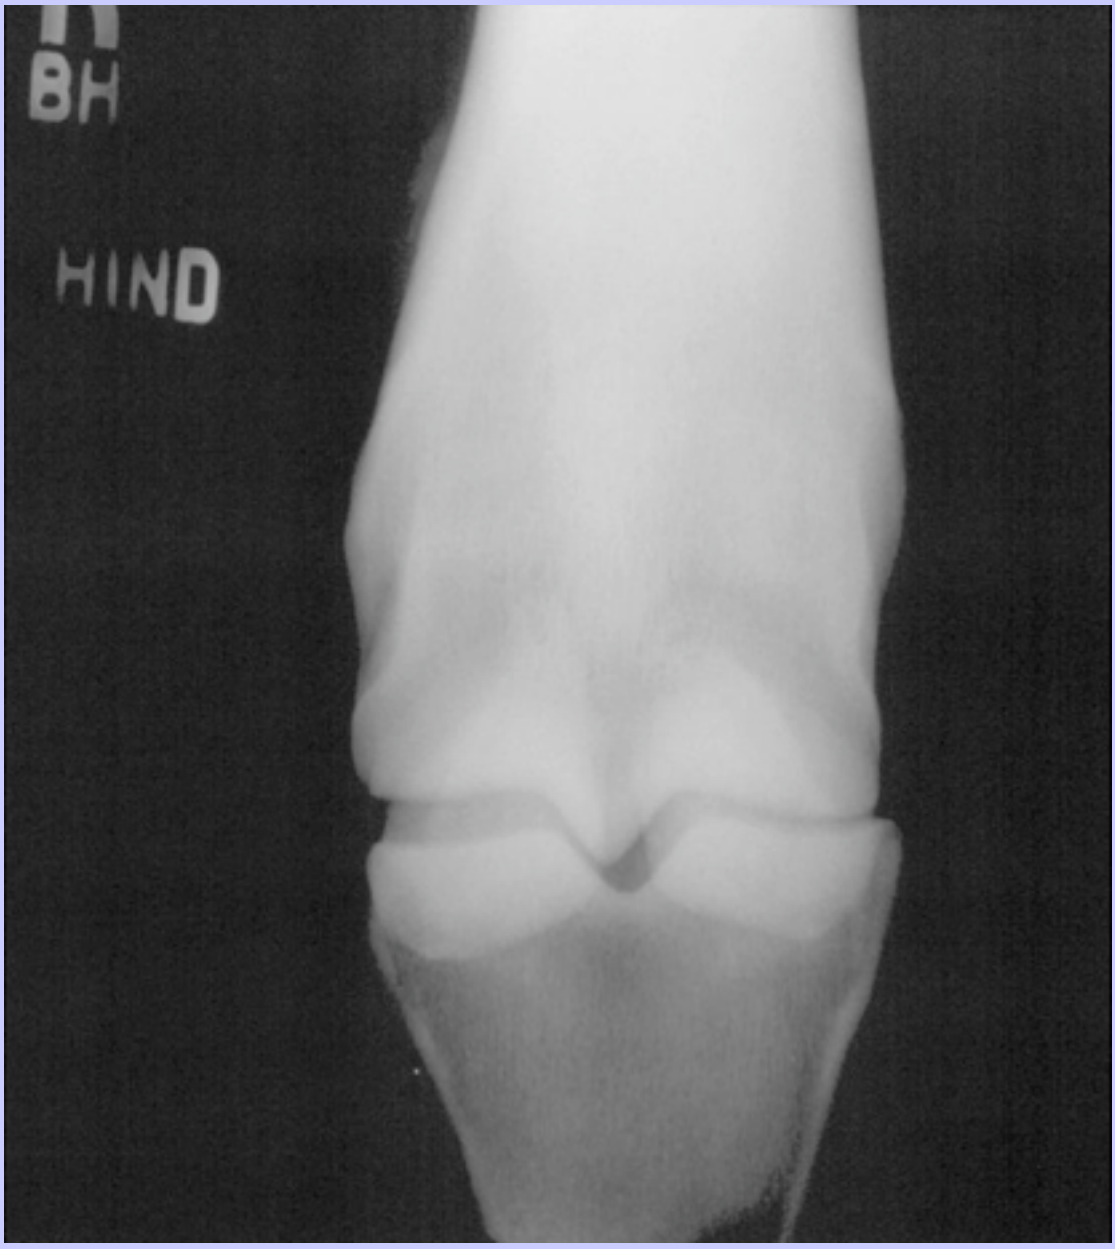
38.9.1 Definitions

Sprains and luxations have been classified as a type 2a traumatic arthritis.[140] These injuries have been categorized in three forms: mild, moderate, and severe. *Mild* sprains constitute injuries that involve the tearing or disruption of minimal number of ligament fibers, with no loss of integrity to the ligament. Hemorrhage and edema typically are present in the ligament. Injuries that involve a portion of the ligament, with loss of integrity, are considered *moderate* sprains. Laxity of the joint is often present with moderate injury; however, complete separation of the ligament from the bone or complete separation of the body of the ligament is not seen. Significant hemorrhage and edema are present in the ligament. Injuries that involve tearing of the ligament, resulting in either complete separation from the bone or widening of the tendon fibers, are considered

severe sprains. These injuries will result in some form of joint instability, especially when the affected joint is manually stressed.

Luxations and subluxtions are usually the result of severe sprains of periarticular or articular ligaments. *Luxations* represent the complete dislocation of the articular surfaces, with *subluxations* having only partial and incomplete disarticulation (Fig. 38-21).

Fig. 38-21 Dorsopalmar radiograph of a subluxated metacarpophalangeal joint after the joint has been manually stressed.



38.9.2 Etiology and Pathophysiology

Sprains can be associated with acute injuries in which there is excessive strain on the ligament fibers, on ligamentous attachments, or secondary to repetitive actions on the ligament. The latter results when there is maximal or near-maximal loads repeatedly applied to the ligaments and associated structures, causing a degenerative type of lesion. Age can also be a contributing factor to these degenerative changes. Furthermore, muscle fatigue can contribute to the weakening of adjacent structures, increasing the stresses applied to the supporting ligaments.

Typically, hemorrhage and edema form within the ligament(s) surrounding the joint capsule, or in severe lesions the hemorrhage can be periligamentous or intraarticular. Inflammation ensues, and the ligamentous or capsular lesion heals through fibrosis, forming a scar, with type III collagen the predominant type produced. Type III collagen contains a smaller fibril diameter and has fewer cross-links then type I collagen, which is the predominant collagen type in normal tendons and ligaments. As the lesion matures, the fibril diameter will increase along with the number of cross-links, in addition to the proportion of type I collagen. This will increase the strength of the injury, which can take weeks to months to heal but will ultimately be weaker than the normal tissue.[141] Often the affected joint capsule and surrounding ligaments become fibrotic as healing occurs, resulting in a decreased range of motion in the affected joint. Secondary calcification of the affected soft tissue structures may occur and adversely affect the joint's mobility.

Luxations of the coxofemoral joint in calves may be associated with calving injuries during a dystocia or in cows being ridden while in estrus, or with a traumatic fall in the immediate postpartum period.[142,143] Shoulder joint luxations are usually the result of trauma.[144]

38.9.3 Clinical Signs and Differential Diagnosis

The clinical signs vary depending on the severity of the sprain and the duration from the initial injury. The animal may have a history of mild lameness or decreased performance, as well as a history of a positive response to NSAIDs or stall rest. Patients with moderate to severe sprains will typically have a more pronounced, acute lameness or may be non—weight bearing on the affected limb. There may also be localized swelling, heat, increased joint effusion, or pain elicited on palpation or manipulation of the affected joint. Other signs may include abnormal limb positioning, decreased range of motion, crepitus, and joint laxity. Injuries may present after an acute or traumatic insult, as a chronic lameness, or a chronic mild injury can present acutely with severe lameness if the ligament completely separates. Chronic injuries are characterized by a thickening of the joint capsule or enthesophyte formation at the origin and insertion of the affected ligament.

Subluxations and luxations result in the loss of joint function and mobility and may present with a varus or valgus deformity. Complete luxations in the horse are most common with the pastern, fetlock, and hock joints.[140] Luxations can occur in the shoulder, carpus, and coxofemoral joint; however, these luxations are less common in horses. Coxofemoral luxations are the second most common type of luxation in cattle.[143]

Differential diagnoses vary depending on the region affected and duration of injury but may include soft tissue contusion, synovitis and capsulitis, osteoarthritis, bursitis, musculotendinous injuries, fractures, physeal fractures, septic arthritis, tenosynovitis, and flexural or angular limb deformities.

38.9.4 Diagnostic Tests

A thorough history and physical examination should be performed at presentation. The exam should include assessment of pain, swelling, heat, effusion, or instability of the joint. Patients able to ambulate with only mild lameness should have a lameness examination that includes perineural anesthesia to localize the affected region or joint. The clinician should take extra caution if there is any evidence of joint laxity or instability or severe lameness.

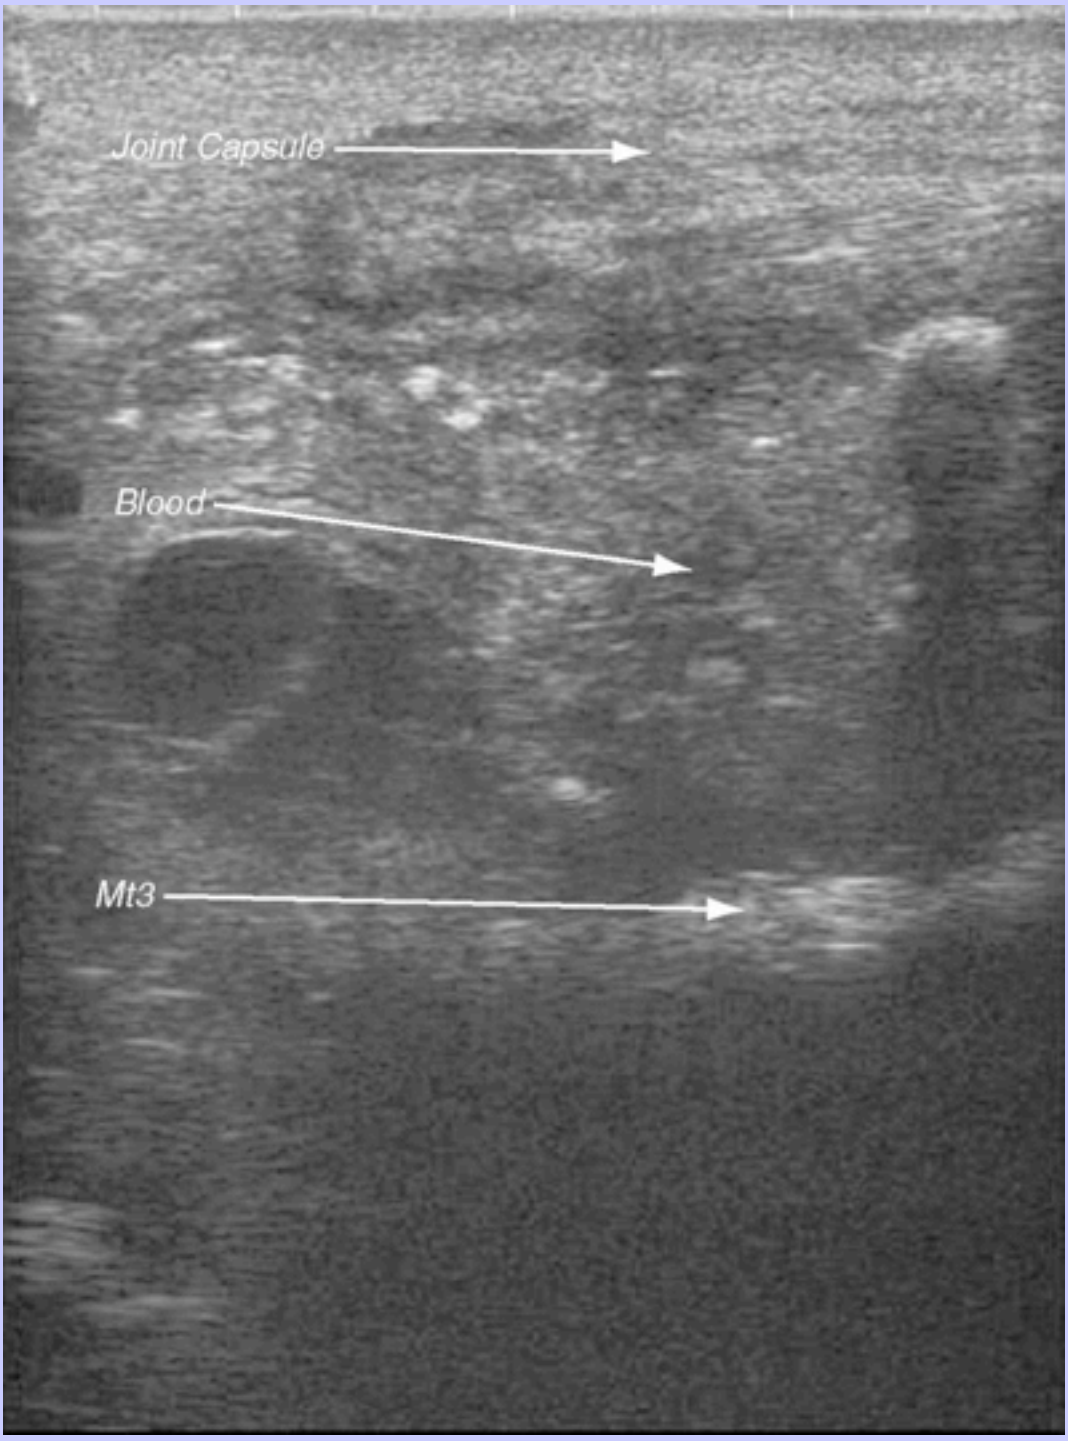
Radiographs should be obtained to assess the bony structures of the joint because concurrent factures are common with traumatic insults resulting in luxation. Stress views can be performed to assess the level of instability of joints (see Fig. 38-21). Fractures of the proximal or middle pastern bones can cause luxation or subluxation of the proximal or distal interpastern joint. Furthermore, radiographs are useful in detecting avulsion fractures or insertional desmopathies and enthesophytes associated with chronic disease. Nuclear scintigraphy can also be used to evaluate insertional desmopathies that may not be radiographically apparent. Arthroscopy may be indicated as a diagnostic aid if disruptions of intraarticular ligaments are suspected or if damage to the articular cartilage is suspected. Ultrasonography is used to locate the ligamentous lesions and characterize the extent of the lesion. Ultrasound should also be used to evaluate the joint because arthritis is a common sequela. Magnetic resonance imaging (MRI) is becoming more readily available in the veterinary field and has been found useful in identifying and characterizing lesions in ligaments. In addition, there may be concurrent damage to adjacent structures of the joint or avulsion fractures that might not be ultrasonographically or radiographically detectable but that can significantly influence the prognosis.[142,145–147]

38.9.5 Treatment

Treatment is largely based on the severity of the lesion and associated structures involved. Mild sprains can be treated conservatively with support bandages, NSAIDs, polysulfated GAGs, and rest for 3 to 4 weeks, followed by a controlled exercise program before returning to normal activity. Adjunctive physiotherapies may also be considered, such as hydrotherapy or shock wave treatment. Moderate sprains involving significant ligament damage may necessitate the use of a cast or splint to provide joint stability during the initial healing process. In acute cases, ultrasound evaluation of the affected joint often shows hemorrhage within the joint capsule (Fig. 38-22). This hemorrhage usually resolves after 7 to 10 days; however, it can also subsequently form a fibrinous clot within the joint capsule, resulting in a chronic mild synovitis that can be treated with intraarticular medications, such as sodium hyaluronic acid, triamcinolone, and amikacin antibiotic. Arthroscopy should be considered to treat joints with persistent fibrin accumulation. Arthroscopy has the advantage of further evaluating damaged cartilage or intraarticular ligaments and serving as a portal for high-volume flush. If arthroscopic surgery is performed, a cast or splint should be applied to the affected limb during recovery from anesthesia to prevent luxation of the affected joint and further injury. Severe sprains may need some form of internal or external coaptation or arthrodesis of the joint, depending on the degree joint instability. Support of the contralateral limb should be considered for non—weight-bearing injuries.

Luxations of the coxofemoral joint in cattle can be repaired by open or closed techniques, and success depends on duration of the luxation, concurrent fractures or soft tissue injury, and age. Open reduction was reported as being more successful than closed reduction, although closed reduction should be attempted immediately after the injury if possible.[143] Shoulder joint luxations can also be reduced by closed and open techniques.[144] Open reduction with internal stabilization seems to result in a better survival outcome for the animal.[144]

Fig. 38-22 Ultrasound image of a metacarpophalangeal joint from a horse with an acute sprain. Note the hemorrhage accumulation within the joint capsule. *Mt3,* Third metatarsal bone of fetlock joint.



38.9.6 Prognosis

Prognosis depends on the severity of damage to the intraarticular cartilage and surrounding soft tissue structures. Horses sustaining mild joint or ligamentous strains have a good prognosis for returning to previous athletic use. Horses sustaining moderate or severe sprains or joint luxations usually develop secondary DJD in the affected joint, which may require intraarticular medications and NSAIDs to return to previous use. The long-term prognosis for returning to athletic performance in these cases is poor. Simple shoulder luxations in large animals generally carry a guarded to poor prognosis. Simple coxofemoral luxations in cattle have a fair to good prognosis, with calves having a better prognosis than adult cows.

38.10 ARTHROGRYPOSIS

K.C. KENT LLOYD

BRADFORD P. SMITH

Arthrogryposis is one of the most frequently encountered congenital diseases affecting calves; foals, goat kids, and lambs are less frequently affected (see also Chapters 51 and 52). The condition is usually characterized by flexural deformity of the interphalangeal, metacarpophalangeal, carpal, and/or metatarsophalangeal joints (Fig. 38-23). Beef breeds are typically affected (e.g., Charolais, Herefords, Simmental), and the incidence is greater in bull calves. The disease is multifactorial in origin and thus often accompanied by other anatomic and neurologic defects, including hydranencephaly, scoliosis, and cleft palate.

1211 1212

Fig. 38-23 Two-day-old heifer calf with bilateral congenital arthrogryposis of the carpus.

Arthrogrypotic diseases can be categorized on the basis of their suspected etiology: infectious (e.g., epizootic bovine and ovine congenital arthrogryposis-hydranencephaly caused by Akabane virus, bluetongue virus, border disease virus, and Cache Valley virus), genetic[148,149](e.g., arthrogryposis and palatoschisis of Charolais calves; arthrogryposis and other abnormalities in Norwegian Fjord horses, Welsh Mountain,[150] merino,[151] and inbred sheep flocks), and toxic[152] (e.g., arthrogryposis in foals associated with Sudan pasture and crooked calf and lamb disease associated with lupine alkaloid). Lambs also may have scoliosis, kyphosis, brachygnathism, and cleft palate.

Cache Valley virus (CVV) is widespread in the western United States and has been isolated in Wisconsin and Michigan; 19% of young sheep from 50 flocks in western states were seropositive. CVV appears capable of causing arthrogryposis-hydranencephaly in fetal lambs.[153] Experimentally infected gnotobiotic lambs developed head tremors and convulsions. Other toxins, as well as lamb manganese deficiency, poisonous plants such as *Solanum dimidiatum,* and sporadic genetic accidents resulting in maldevelopment, also are associated with arthrogryposis and related defects.

Despite numerous causes, the clinical features of arthrogryposis are similar. Varying degrees of irreducible and rigid flexural deformity of both carpi and forelimb fetlock joints are more frequently observed than hyperextension of the tarsus, flexural deformity of the hindlimb fetlocks, or tetramelic arthrogryposis. In contrast, flexural deformities caused by contracted tendons are not associated with improper articular alignment or rotational deformity, and the limb often can be straightened manually. Flexural deformities that could be confused with arthrogryposis may be secondary to septic arthritis or fracture (Box 38-1).

Rigid flexural deformity is a common cause of dystocia in cattle and horses. Failure to straighten a flexed limb manually through the vagina usually indicates the need either for cesarean section or fetotomy if the fetus is dead. Forced extraction is dangerous to the dam, because during the procedure the flexural deformity may cause damage to the uterus, cervix, and vagina. Depending on the etiology, other defects are observed in association with arthrogryposis (Table 38-2). The most frequently observed triad of signs is arthrogryposis, scoliosis, and cleft palate in Charolais calves.[148,154]

38.10.1

Box 38-1 Mechanisms of Joint Immobility and Arthrogryposis

Agenesis of ventral motor horn cells of spinal cord

Fractures involving one or more joints

Severe joint or tendon swelling

Contracture of muscles or tendons

Septic arthritis

Ankylosis

Skeletal neoplasia

Agenesis or dysgenesis of joint structures

Table 38-2 Other Defects Associated with Arthrogryposis Syndromes

Disease	Related Signs
Epizootic bovine congenital arthrogryposis—hydranencephaly (Akabane virus—exotic)	Incoordination, hydranencephaly, blindness, abortion, microencephaly
Arthrogryposis and palatoschisis (genetic in Charolais breed)	Cleft palate, hydrocephalus, kyphosis, scoliosis, hypoplastic patella
Crooked-calf disease (lupine toxicity)	Scoliosis, torticollis, cleft palate
Hereditary arthrogryposis	Kyphosis, torticollis, scoliosis, cleft palate

The pathogenesis of arthrogryposis is speculated to be related to restricted fetal movement in utero as a result of mechanical limitations, agenesis of α-motoneuron cell bodies in the ventral horn of the sixth cervical segment of the spinal cord, and radial nerve dysfunction.[148] Agenesis of some motoneuron cell bodies may result in lack of normal fetal movement, hypoplastic musculature, and frozen joints.[155] The cause for agenesis of motor horn cells in the spinal cord in unknown, but in virus-associated outbreaks it is probably virally induced.

Treatment of mildly rigid flexural deformities may be effective if joint mobility and the ability to stand progressively improve over several days. Passive stretching and flexing of the affected limbs, bandages, splints, and later casts may be beneficial. Vitamin E and selenium supplementation has been suggested, but the only mineral deficiency associated with arthrogryposis is manganese.[154] Surgical techniques also have been described for transection of the flexor retinaculum and flexor tendons and for excision of the carpal bones with arthrodesis of the joint, depending on the location and severity of the deformity. These procedures are intended to salvage the animal for rearing to market weight. Calves with suspected inherited deformities should not be returned to breeding stock.

38.11 ANKYLOSIS

TAMARA M. SWOR

38.11.1 Definition and Etiology

Ankylosis is the abnormal adhesion or fusion of the bones in a joint. This process is naturally occurring, resulting in a consolidation of two or more bones into one structure.[156] Development of ankylosis is often the result of disease or traumatic injury to the region involved. Septic arthritis may be an inciting factor for secondary ankylosis, as can DJD, severe articular or periarticular trauma, and prolonged joint immobilization from bandaging, splinting, or casting.[157,158] *Congenital ankylosis* (absence of an articulation) may occur, but it is rare in horses and cattle and is often associated with other congenital abnormalities.[159]

The process of joint fusion is initiated by biomechanical and biochemical factors, leading to joint instability and degeneration of cartilage and chondrocytes. Joint immobility occurs from periarticular contracture, capsular fibrosis, and chronic muscle spasm, leading to synovitis and cartilage destruction. Ossification of the periarticular soft tissue structures begins to develop, resulting in partial bone bridging of the joint. The final stage of ankylosis is complete bone bridging with trabecular bone and joint obliteration.[160]

Common sites of ankylosis in the horse include the tarsometatarsal joint, distal intertarsal joint, thoracolumbar intervertebral articulations, proximal interphalangeal joint, and distal interphalangeal joint. In high-motion joints, naturally achieving complete bony bridging across the articular surface is rare, and the resulting cartilage degeneration leads to severe lameness.[156] Low-motion joints are more likely to achieve complete ankylosis without intervention. Large animals with vertebral ankylosis may show neurologic deficits caused by bony impingement of the spinal cord or by dynamic compression leading to abnormal motion or spinal ligament hypertrophy.[160] Pathologic fractures may occur near joints that are ankylosed because of abnormal biomechanical forces on the limb, and animals are prone to secondary injuries and osteoarthritis from abnormal stresses imposed on neighboring normal joints.[161]

Facilitated ankylosis refers to a procedure in which the joint is stimulated by a method intended to promote joint fusion. The speed at which ankylosis occurs may be enhanced through the use of chemical destruction of the chondrocytes or surgical obliteration of the joint.[162] A recent study evaluating surgical drilling to achieve ankylosis of the distal intertarsal joint and tarsometatarsal joint reported that 59% of the horses were sound and able to perform at their previous level of athletic performance.[163] A neodymium:yttrium-aluminum-garnet (Nd:YAG) laser has also been used for facilitated ankylosis in the distal tarsal joints.[164] Chemical fusion options include the use of ethyl alcohol or sodium monoiodoacetate (MIA) injected into the intraarticular space.[156,162,165] A study comparing surgical drilling, laser surgery, and injection of MIA into the distal tarsal joints revealed that bone bridging was greater in the MIA and surgically drilled horses at 6 and 12 months after treatment; however, animals receiving laser treatment were more comfortable after surgery and less lame on the treated limb.[156,164] Injection of 70% ethyl alcohol into the tarsometatarsal joint of healthy horses resulted in progression to joint fusion 4 months posttreatment, although complete obliteration of the joint had not occurred by 12 months after treatment.[162]

Arthrodesis involves surgical fixation of a joint using procedures designed to promote joint fusion. An arthrodesis therefore may be considered a type of ankylosis.[156] A typical arthrodesis involves the use of stainless steel screws and dynamic compression plates, after removal of the articular cartilage.[156]

38.11.2 Clinical Signs and Differential Diagnosis

Typical indications of ankylosis include fused joint bones evident on radiography, stiffness of the joint and joint immobility, and decreased range of joint motion. Limited joint mobility is most obvious if high motion or multiple joints are involved. In the early stages, there may be local signs of inflammation with a corresponding lameness. The degree of lameness ranges from mild to severe. Enlarged and thickened periarticular structures, conformational abnormalities, disuse atrophy of muscles, and gait stiffness may also be identified. Once ankylosis is complete and no cartilage remains, the condition is nonpainful and the articulation will be immobile.

In calves and foals, congenital ankylosis may occur between vertebrae (i.e., block vertebrae) or in multiple joints of the limbs, resulting in dystocia related to musculoskeletal inflexibility.[160]

Differential diagnoses should include soft tissue injuries or contracture, intraarticular or periarticular adhesions, luxation of a joint, joint or bone neoplasia, arthrodesis, spondylosis, an intraarticular mass, osteomyelitis, and fracture. Diagnosis of ankylosis should be based on a complete physical examination, lameness evaluation, and radiographs. Multiple radiographic views should be acquired for definitive diagnosis; however, other imaging techniques such as ultrasonographic evaluation, computed tomography (CT), and MRI may be useful and provide more detailed information.

38.11.3 Treatment and Prognosis

Early treatment focuses on making the animal comfortable because ankylosis is a chronic and progressive disease process. Treatment may include antiinflammatory medications, polysulfated polysaccharides (Adequan), hyaluron, oral joint supplements, joint immobilization, and a decrease in the level of athletic performance required. Common antiinflammatory medications include systemic phenylbutazone and intraarticular administration of corticosteroids.[162] A low level of exercise appears to be beneficial in some animals and may increase and stimulate the development of new bone, resulting in a more rapid and complete ankylosis. In unstable joints, immobilization with splints or casts may be necessary to allow the fusion to progress. Although further studies are warranted, the neurolytic properties of intraarticular 70% ethyl alcohol may allow the horse to continue in athletic work during the fusion process.[162] In horses that remain lame, have end-stage joint osteoarthritis, or are not completing ankylosis naturally, facilitated ankylosis and arthrodesis are viable treatment options that may result in a usable animal.

Ankylosis may require 6 to 12 months for completion and in some animals may take longer.[158,165] Prognosis depends on which joint is involved and the intended use of the animal. Low-motion joints (distal tarsal joints in horse) hold a good prognosis for return to soundness and athletic activities after completion of the fusion process. Animals requiring the use of a high-motion joint to sustain their athletic career have a poor prognosis for return to function. Once the bony bridge is complete, ankylosis is not painful, but it is irreversible, and joint mobility is absent.

38.12 OSTEOMYELITIS

PATRICIA A. HOGAN

CLIFFORD M. HONNAS

38.12.1 Definition and Etiology

Osteomyelitis is an infectious inflammatory disease of the substance of bone and its marrow cavity. Most large animal bone infections are of bacterial origin; mycotic infections rarely occur. Osteomyelitis may be acute or chronic and may involve the epiphyseal, metaphyseal, or diaphyseal region of a bone. Osteomyelitis can originate hematogenously, secondary to a contiguous focus of infection, or by direct bacterial inoculation (e.g., trauma, orthopedic surgery).[166,167]

38.12.2 Clinical Signs and Differential Diagnosis

Diagnosis is based on history, physical examination findings, microbiologic culture results, and radiographic findings. Clinical signs vary with the length and severity of infection and the organism involved.

Animals with acute osteomyelitis usually exhibit localized inflammation and soft tissue swelling, may resent palpation of the affected area, and often have an obvious lameness. Fever, anorexia, depression, and general malaise may be observed. Acute bacterial osteomyelitis is seen most often in very young animals and is usually of hematogenous origin.[166,168] In the neonate it is frequently secondary to other foci of infection (e.g., respiratory or gastrointestinal tract) or umbilical remnant.[168] There is often a history of prematurity, failure of passive transfer of colostral immunoglobulins, or peripartum difficulties. Osteomyelitis in foals, calves, kids, and lambs is typically associated with septic arthritis and may or may not involve infection of the epiphyseal, physeal, and metaphyseal regions of the long bones.[168]

The acute form of osteomyelitis is rare in adults and usually is associated with direct bacterial inoculation during trauma or open reduction of a fracture. Clinical signs of fever, localized pain, inappetence, and soft tissue swelling often make differentiation between infection and postoperative inflammation difficult. Persistent elevation in rectal temperature for more than 48 hours may be more indicative of an acute infectious process.

Fever and depression are usually not observed in chronically affected animals. In adults, infection is usually localized and the result of direct trauma to bone. Clinical signs typically observed in chronic osteomyelitis include firm swelling of the affected area, reluctance to bear weight on the limb, mild to moderate lameness, and presence of a draining fistulous tract. Drainage may be constant or intermittent and is usually purulent.

Radiographic signs of acute osteomyelitis are often subtle and can be difficult to interpret. Soft tissue swelling adjacent to the affected area may be the only radiographically visible abnormality during the initial signs of infection. Osteolysis may be observed as early as 3 days; however, serial radiography is often necessary to visualize bony changes, which may lag 7 to 14 days behind the evolution of infection.[168] Destruction of cortical bone initially appears as focal radiolucent holes that subsequently enlarge and coalesce to involve a region of bone (Fig. 38-24). Radiographic changes frequently noted in animals with chronic osteomyelitis include sclerotic bone, cortical resorption and thinning, and periosteal proliferation that may be smooth, expansile, or spiculated.[166] A *sequestrum,* a necrotic portion of cortical bone devoid of an osseous blood supply, is a classic radiographic observation. It appears radiodense and is surrounded by an area of cortical lysis[169] (Fig. 38-25). As the body's defenses attempt to isolate the area of infection, periosteal new bone forms an *involucrum,* or bony sheath, around the sequestrum with a cloaca that allows inflammatory debris an avenue to egress through a fistulous tract to the skin[169] (Fig. 38-26).

Osteomyelitis at a fracture repair site delays healing and fracture instability is often noted clinically. Radiographically, lysis or bone resorption around implants may be observed, and fracture gap widening or nonunion is frequently seen.[166] Implant loosening and fixation collapse may occur with progression of bone lysis.

Fig. 38-24 Osteomyelitis of the distal metaphyseal, physeal, and epiphyseal regions of the third metacarpal bone of a 3-week-old foal that did not receive colostral immunity at birth. Bony destruction is advanced. Note the associated soft tissue swelling.

Fig. 38-25 Cortical sequestration of the dorsal aspect of the third metatarsal bone in a horse 4 weeks after blunt trauma to the region.

1214

Fig. 38-26 Lateral radiograph of the third metacarpal bone of a cow with chronic osteomyelitis. A sequestrum is visible surrounded by an area of osteolysis. An involucrum formed by medullary sclerosis and periosteal new bone and a cloaca *(arrows)* are evident.

A definitive diagnosis of osteomyelitis is made by culture of the suspected focus of infection. Samples for culture may be obtained from deep needle aspirates, sequestra, and necrotic tissue removed during surgical debridement or metallic implants removed from the affected area. It is not recommended to culture draining tracts because tract organisms are not usually the pathogen(s) responsible for bone infection. Blood cultures are advisable in the neonate. Culture for both aerobic and anaerobic bacterial pathogens is indicated. Clinical characteristics suggestive of, but not limited to, anaerobic infection include a fetid odor, presence of bony sequestra, and purulent discharge. Anaerobic infection should be suspected if bacteria are identified on cytologic analysis but routine aerobic cultures show no bacterial growth.[166] Anaerobes are frequently associated with infection after surgical repair of an open fracture. Culture results will most accurately reflect the causative bacteria if samples have been collected and transported properly.

38.12.3 Clinical Pathology

The WBC count is usually elevated in animals with acute osteomyelitis. A degenerative left shift in the leukogram is often present. In neonates an initial leukopenia may be observed as the result of a primary disorder such as generalized septicemia or enteritis. Plasma fibrinogen also may be elevated in acute infection. The leukogram tends to return to normal with chronicity.

Osteomyelitis is frequently associated with septic arthritis in the neonate.[167,168] Synovial fluid of affected joints has an elevated leukocyte count and total protein concentration. Gram stain of synovial fluid can be helpful initially in determining the type of bacteria present, to aid in the selection of appropriate antimicrobial therapy before culture results are known. Blood cultures also may be helpful for identification of causative organism(s) in the neonate.

38.12.4 Pathophysiology

Sequestration of cortical bone results from mechanical trauma to the periosteum and overlying soft tissues, which compromises the defenses of normal cortical bone and leads to regional vascular injury and venous stasis.[166,167,169] Increased capillary permeability permits inflammatory cells to infiltrate the injured area and engulf bacteria. Lysed neutrophils release proteolytic lysosomal enzymes that induce local tissue and bone necrosis; and an exudate composed of serum, neutrophils, bacteria, and nonviable tissue accumulates.[167] If host defense mechanisms are inadequate to contain the infection, bacterial colonization of adjacent periosteal, cortical, and medullary regions ensues.[167] Antibodies and antibiotics cannot easily penetrate the infected area because of the compromised blood supply. The necrotic cortical bone or sequestrum is enveloped by granulation tissue and new bone, forming an involucrum in an effort to contain the infection.[167] Draining sinus tracts may eventually form as the disease progresses. Acute hematogenous osteomyelitis has historically been attributed to sluggish blood flow in the metaphyseal region of long bones in young, growing animals.[166,167] It was thought that vascular stasis in the capillary loops of the primary spongiosa resulted in localization of blood-borne bacteria in the metaphysis. Recently it has been shown that the endothelial lining of the capillaries pervading the primary spongiosa of neonates is incomplete and allows extravasation of bacteria and erythrocytes.[166] Because leukocytes are absent from this location in the young animal, macrophages provide the sole defense against bacterial colonization in this region.[166] The inability of these macrophages to eliminate bacteria effectively appears to be a critical factor in the development of hematogenous osteomyelitis in young animals.

38.12.5 Treatment

Selected cases of acute osteomyelitis may respond to aggressive antimicrobial treatment in the early stages, but once infection is established in bone, it is difficult to resolve without surgical intervention. Broad-spectrum antimicrobial administration in combination with surgical management constitutes the hallmark of treatment for osteomyelitis.[166,167]

The goal of surgical treatment is to facilitate the penetration of blood-borne antibiotics to the site of infection by eliminating necrotic debris and encouraging vascular access to compromised tissues. The most important precepts are careful and thorough debridement of all nonviable tissue and sequestrated bone fragments, establishment of open drainage, and removal of foreign material implants.[166,167] Certain bacteria (e.g., staphylococci) are capable of producing a viscous substance that enshrouds bacterial colonies and facilitates adhesion of bacteria to necrotic bone and foreign implants.[166] When combined with host-derived matrix proteins and cellular debris, this biofilm protects bacteria from host defenses and may actually alter bacterial susceptibility to certain antibiotics.[166]

The exception to implant removal arises when the implant is required for fracture stabilization. Although healing is delayed, stable fractures can heal in the presence of infection.[166] Therefore it is advisable to maintain implants until they are no longer necessary for fracture stability while treating the infection. However, delayed healing can lead to excessive cycling of the implant and fixation failure.

Initially the choice of appropriate antibiotic is based on known susceptibilities of the organism suspected to be responsible for infection. Antibiotic therapy may require modification after a definitive organism(s) is isolated and in vitro susceptibilities determined. The ideal antibiotic demonstrates the greatest bactericidal activity against the offending organism, with the least toxicity to the patient, and is economically feasible. Duration of antibiotic therapy is empirical and depends on clinical response. Because compromised bone requires 4 to 6 weeks for revascularization, this time frame has generally been accepted for treatment duration in cases of chronic osteomyelitis.[166,170]

1215 1216

The most common aerobic bacterial groups isolated from musculoskeletal infections in horses include Enterobacteriaceae, streptococci, and staphylococci.[171] *Actinomyces pyogenes* is the most frequent isolate recovered from adult cattle, sheep, and goats. Neonates appear particularly susceptible to infection from *Escherichia coli* and *Salmonella* species.[168] *Bacteroides* species is the most predominant obligate anaerobic genus encountered; however, most infections include a mixture of anaerobes or a combination of aerobes and anaerobes.

Parenteral administration of antibiotics constitutes the mainstay of antimicrobial therapy in the treatment of osteomyelitis.[170] Localized antibiotic therapy, however, is a useful adjunct to systemic antibiotic treatment. Regional limb antibiotic perfusion, local implantation of polymethylmethacrylate (PMMA) antibiotic-impregnated beads, and use of autogenous cancellous bone grafts enhance the resolution of osteomyelitis.[172–174]

Regional limb perfusion delivers a systemic dose of antibiotic to an isolated area of infected tissue,[172,173] subjecting the tissue to antibiotic concentrations in excess of the MIC for the infectious agent. This technique is particularly useful for cases of septic arthritis in which vascular compromise of synovial membrane may

prevent adequate antimicrobial distribution.[172] A tourniquet is placed proximal to the site of infection. A systemic dose of antibiotic is administered through a catheterized vein distal to the site of infection,[172,173] or through a single, 4.5-mm-diameter hole into the medullary cavity and allowed to perfuse the isolated area for 30 minutes. In horses, cattle, and rabbits, synovial antibiotic concentrations are significantly greater than peak serum concentrations associated with systemic administration.[172,173] We have used regional limb perfusion as an adjunct treatment in selected cases of septic tenosynovitis and navicular bursitis and osteomyelitis of the calcaneus, phalanges, and distal sesamoid bone.

Antibiotic-impregnated PMMA beads are an effective drug delivery system for bone and soft tissue infections in human medicine.[166,174] Although this treatment is gaining popularity in large animal orthopedics, there are no published reports of its efficacy in veterinary medicine. Gentamicin is the traditional antibiotic impregnated in beads and elutes over time to yield local concentrations well above the therapeutic concentration range for as long as 80 days postimplantation.[174] Aminoglycoside toxicity does not appear to be a problem, with human serum and urine concentrations below those associated with systemic administration.[174] Gentamicin-impregnated PMMA beads are used routinely in our hospital in the repair of open fractures and in the internal fixation of closed fractures that incurred significant soft tissue trauma.

The use of autogenous cancellous bone graft has been advocated as an ancillary treatment in some cases of septic navicular bursitis and osteomyelitis of the navicular bone in horses.[175] Placement of the graft in a surgically created defect underlying the navicular bone may reduce dead space, provide protection of the deeper tissues from environmental contamination, and afford a temporary scaffold for the ingrowth of capillaries and precursor cells of granulation tissue.[174] We believe this modality has merit for continued clinical application and routinely use it for deep-seated infections of the foot.

38.12.6 Prevention and Control

Early and aggressive medical therapy for neonates suspected to be at risk for developing septicemia is prudent in the prevention of acute hematogenous osteomyelitis. Therapy may include administration of prophylactic antibiotics and hyperimmune plasma in animals with failure of passive transfer of colostral antibodies. Prompt and meticulous debridement of avascular and necrotic tissue in treatment of soft tissue wounds and repair of open fractures cannot be overemphasized. Delayed wound closure may be desirable in select cases of overwhelming contamination or infection.

Many infections associated with fracture repair occur during open reduction and internal fixation of closed fractures.[166] Strict adherence to the principles of aseptic technique is imperative to a successful outcome. Prophylactic antibiotics are often used because the risk of infection increases with metallic implants. The timing of antibiotic administration is crucial for efficacy and should achieve sufficient blood antibiotic levels while the amount of bacteria in the exposed tissues exceeds the host's ability to eliminate the organisms and allow tissue healing to commence.[167] For elective uncomplicated orthopedic procedures, antibiotics should be administered 1 to 2 hours before surgery and continued for no more than 72 hours after surgery.[167] For long-bone fracture repair, the risk of infection is much greater because of increased operative time, the presence of metallic implants, and the soft tissue trauma incurred during the injury and subsequent fixation.[171] In this case, administration of the most effective broad-spectrum antibiotic combination for an extended period is advisable.

38.13 NAVICULAR DISEASE (PALMAR FOOT PAIN)

ROBIN M. DABARIENER

Approximately one third of all forelimb lameness in horses originates from the caudal third of the foot. Lameness originating from this area has generally been associated with pain arising from the navicular bone and its related structures, although other structures in the foot can also cause lameness. Any one or combination of the following structures should be considered as a potential source of injury in horses that exhibit lameness localized to the posterior aspect of the foot:

1. The navicular bone itself.
2. Desmitis of the navicular suspensory apparatus, which includes the sesamoid impar ligament (IL) distally and the collateral suspensory ligament (CSL) proximally.
3. Synovial membrane of the navicular bursa; navicular bursitis or inflamed tissue (adhesions) between the navicular bursa and DDFT.
4. Desmitis of the deep digital flexor tendon (DDFT) at (a) the insertion, (b) palmar to the navicular bone, or (c) proximal to the navicular bone.
5. Laminar tearing in the heel region.
6. Solar bruising in the heel region.
7. Some aspects of the palmar region of the distal phalanx.
8. Synovial structures located in the distal interphalangeal (DIP) joint.
9. Structural damage to the hoof capsule in the heel region (e.g., underrun heels, collapsed foot).
10. Desmitis of the distal annular ligament.

38.13.1 Diagnosis

The diagnosis of heel pain is not difficult when a horse's lameness resolves with a palmar digital nerve block. 1216
However, determining which foot structure is the source of pain and establishing correct treatment are 1217
becoming more difficult. It seems that the more we learn about diagnostic anesthesia, the more clouded the picture becomes. Horses with navicular or heel pain can be a diagnostic and therapeutic challenge to the owner, clinician, and farrier.

Diagnosis is based on historical data, clinical findings, and both routine and advanced imaging techniques to localize the structure causing pain within the hoof capsule. My approach to horses with lameness originating from the heel region is to determine which structure in the foot is causing the pain and then develop a therapeutic plan. Severity and duration of the lameness, the horse's activity, and potential owner compliance, as well as the farrier's experience, should be considered. The horse's hoof wall quality, conformation, environment, and occupation will all affect therapy.

38.13.2 HISTORICAL DATA

Common complaints reported by owners of a horse exhibiting chronic foot pain include intermittent unilateral or bilateral forelimb lameness and increased severity of lameness for several days immediately after shoeing or at the end of the shoeing period (when the toes are long). Occasionally the horse may point the affected forelimb, stumbling, with a short, choppy gait and increased lameness when ridden on hard ground.

Horses sustaining acute injuries to soft tissue structures in the caudal aspect of the foot (e.g., impar or CSL of navicular suspensory apparatus, distal DDFT), laminar tearing, or severe bruising of the heel region may have a history of becoming acutely lame during or immediately after a performance event. Historical data are often overlooked but may suggest which foot structure is damaged.

38.14 Clinical Findings and Diagnostic Evaluation

Signalment can be helpful in the diagnosis of chronic heel pain. Middle-aged quarter horses and thoroughbred and warmblood horses in general are often affected by navicular disease. Arabians, draft horses, ponies, donkeys, and mules are rarely affected with palmar foot pain. A hereditary predisposition may be related to the development of navicular disease. Many quarter horses are heavily muscled and have relatively small hoof size. Poor hoof conformation plagues many thoroughbred and warmblood horses. Since 1978, Dutch warmblood stallions with grade 4 classification on navicular bone radiographs (0 = excellent, grade 4 = poor) have not been certified for breeding. The incidence of grade 3 or 4 navicular radiographs has decreased from 11% in 1997 to 3% in 2002.[176] Although hindfeet can be affected with navicular disease, it is predominantly considered a forelimb problem.

Observation of limb conformation, as well as hoof size and shape and hoof-pair asymmetry, can aid in the diagnosis and treatment of palmar foot pain. A broken back hoof-pastern axis is frequently seen in horses with navicular or heel pain, but a small subset of horses with navicular pain will have a broken forward or normal hoof-pastern alignment. In one report of horses diagnosed with navicular disease, 72% had a broken back hoof-pastern axis and 8% a broken forward axis.[177] Horses having a long-toe, low—heel-hoof conformation or underrun heels (defined as >5 degrees difference between heel and toe angle of foot) was reported in 77% of a group of horses with chronic heel pain.[177] Atrophy of the frog and contracted heels (defined as frog width less than two-thirds its length) can be seen in horses with palmar foot pain and has been attributed to lack of weight bearing in the posterior portion of the foot, which reduces the dynamic movement of the frog.[177] Hoof-pair asymmetry in which one foot is smaller, narrower, and has a higher heel length is also common in horses with navicular area pain. The smaller and more upright foot is usually the lamest limb.

A thorough musculoskeletal examination should include palpation and comparison of the digital pulses in the feet and assessment of the hoof capsule for increased heat. Of 23 horses diagnosed with navicular area pain, 97% had an increased digital pulse in the most severely affected limb.[178] Hoof tester evaluation can be beneficial in determining pain location. Pain involving the navicular area is identified by application of intermittent hoof-tester pressure over the middle third of the frog, which results in persistent, nonfatigable reflex withdrawal of the hoof from the examiner. It is important to assess if the withdrawal reflex is resulting from real pain and not a whimsical reaction by the horse. Both front feet should be tested and results from each foot compared. A positive hoof-tester response over the wall of the foot across the ends of the navicular bone may occur in horses with radiographic evidence of proliferative new bone on the abaxial margins of the navicular bone. Horses sustaining an injury to the impar ligament or insertion of the DDFT seem particularly sore with hoof tester pressure near the junction of the middle and anterior thirds of the frog. Horses with underrun heels, bruised heels, or damaged laminae in the

heel area will often have more pain over the affected heel. It is important, if possible, to differentiate peripheral versus central hoof pain with a thorough hoof tester examination. Many horses with heel pain will land toe first and may bruise the sole in the toe region, resulting in pain from hoof testers in this area. The hoof-tester exam is a useful diagnostic tool, but horses can have navicular area pain and not respond to hoof tester pressure. This will occur more often during periods of dry weather, when the horse's feet are excessively hard, or in horses with thick soles and hard frogs.

38.14.1 LAMENESS EXAMINATION

Horses with bilateral forelimb involvement have a stiff, shuffling, short-strided gait that owners often perceive as shoulder lameness. The horse should be observed at a slow trot in a straight line and circled in both directions. A smooth, hard surface is optimal. In horses with heel pain the lameness will often be exacerbated when trotted on hard versus soft ground. The severity of lameness should be assessed before and immediately after application of hoof-tester pain. Horses with navicular area pain may have increased severity of lameness when trotted after the hoof-tester application in the central frog area. Several tests may exacerbate lameness in horses with navicular pain, such as allowing the horse to stand on a small block of wood centered over the frog for 60 seconds before trotting, or elevating the toe with a block of wood. A 30-second lower-limb “fetlock” flexion test may also exacerbate lameness in horses with navicular area pain.

38.14.2 DIAGNOSTIC ANESTHESIA

Perineural anesthesia of the palmar digital nerves (PDNs) with 1 to 2 mL of mepivacaine placed axial and distal to the proximal limits of the medial and lateral collateral ligaments will desensitize the palmar half of the foot, entire sole, and palmar aspect of the coffin joint. This block is performed just below the proximal limits of the collateral cartilages to avoid desensitizing the dorsal nerve branches. One study demonstrated that lameness secondary to solar pain created by a setscrew-induced pain model was eliminated 10 minutes after anesthesia using 2 mL mepivacaine over each PDN.[179] In the past, coffin joint (DIP) anesthesia was thought to be helpful in diagnosing navicular area pain, but investigators have recently demonstrated a lack of specificity with this block. DIP anesthesia has been shown to eliminate lameness associated with pain in the navicular bone itself, navicular suspensory apparatus, navicular bursa, and sole of the foot, because the sensory nerves to the navicular area are close to the DIP joint, and passive diffusion of the anesthetic occurs to the PDNs. Solar pain in the toe region was eliminated before solar pain in the heel region after DIP anesthesia, and a maximum 6 mL of anesthetic was recommended for analgesia of the DIP joint. This suggests that horses with heel bruises or laminar tearing in the heel region should not improve after DIP analgesia using low-volume anesthetic and evaluating the horse after 10 minutes.

1217

1218

The navicular bursa is a thin synovial structure located between the navicular bone and distal aspect of the DDFT. Analgesia of the navicular bursa may be more specific for navicular area pain. A positive response to navicular bursa analgesia probably reflects pathology in the navicular bursa, navicular bone, or supporting ligamentous structures. The normal navicular bursa has a 3-mL capacity, which may be reduced in horses with inflamed tissue or adhesions between the navicular bursa and DDFT. Synovial fluid is obtained infrequently when performing navicular bursa analgesia.

Horses that improve but do not have total resolution of the lameness until after a high palmar digital or abaxial nerve block may have pain associated with a desmitis of the DDFT within the hoof capsule or desmitis of the DIP joint collateral ligament. Horses with DDFT desmitis may also improve after DDFT analgesia.

38.14.3 RADIOGRAPHIC EXAMINATION

A minimum of three high-detail radiographic views should be used to evaluate the navicular bone; additional views are needed to evaluate the entire foot. Lateromedial (LM), 60-degree dorsoproximal-palmarodistal oblique with grid (D60Pr-PaDiO), and palmaroproximal-palmarodistal oblique (Pa45Pr-PaDiO) views of the navicular bone are obtained. Some clinicians also include two oblique views of the navicular bone. Abnormal radiographic changes include variation in size and shape of synovial foramina on the D60Pr-PaDiO projection; cystic changes within the navicular bone; enthesophyte formation at the attachment of the CSL ligament on the LM projection; flexor cortex erosions and loss of corticomedullary distinction, best viewed on the Pa45Pr-PaDiO projection; calcification of the flexor surface and distal DDFT; and osseous fragments associated with avulsion of the impar ligament. Previous studies have shown that abnormal synovial fossae are poorly correlated with lameness, rarely progress over time, and are inconclusive for the diagnosis of navicular disease. Radiographic abnormalities more strongly associated with lameness are flexor cortex defects, medullary sclerosis, proximal border remodeling, and loss of medullary trabecular pattern.

Although radiographic evaluation is important in the diagnostic workup of a horse showing palmar foot pain, it is not very sensitive in defining the actual pathologic condition of the navicular bone. Radiographs often underestimate the extent of pathology seen on necropsy in horses with navicular lesions.

38.14.4 NAVICULAR BURSOGRAPHY

Administration of a 3-mL mixture of 1:1 contrast media and anesthetic into the navicular bursa, followed by a Pa45Pr-PaDiO radiographic view, is used to evaluate pathologic changes on the flexor surface of the navicular bone and adhesions or scarring of the DDFT. The advantage of this technique is confirming pathologic changes on the flexor surface of the navicular bone, which may not be apparent on survey radiographs, and injection of the anesthetic into the navicular bursa. Navicular bursography identified pathology in the flexor region of the navicular bone 60% more often than plain radiographs.[179a] The disadvantages are that some horses are not very tolerant of needle penetration of the DDFT and insertion into the navicular bursa, and the procedure carries risks such as trauma to the navicular bone, sepsis, acute synovitis of the bursa, and possibly DDFT damage secondary to needle penetration.

38.14.5 NUCLEAR SCINTIGRAPHY

Radiography has lower sensitivity than, but equal specificity as, scintigraphy for the diagnosis of navicular disease. For detecting abnormal bone activity within the hoof, nuclear scintigraphy is a sensitive but rather nonspecific imaging method. Scintigraphy detects increased ^{99m}Tc uptake in areas of active osteoblastic activity; however, because of the proximity of anatomical structures in the caudal third of the foot, specific structural location of the source of pain in a horse with palmar foot pain is limited with scintigraphy. The reliability of scintigraphy in diagnosis of foot pain has been criticized because of common false-positive and false-negative results. Lateral bone-phase images were found to be less sensitive than palmar images, and views taken 1 hour after radioisotope administration were as diagnostic as those taken 2 to 4 hours after administration.

38.14.6 ULTRASONOGRAPHY

Diagnostic ultrasonographic images can be obtained for some structures in the foot region. Ultrasonographs of the collateral ligaments of the DIP joint are obtained by positioning a 7.5- or 10-MHz transducer on the firm part of the dorsolateral and dorsomedial aspects of the coronary band. The normal DIP joint collateral ligament for a large horse is about 0.66 cm.[177] The distal aspect of the DDFT can be visualized from between the heel bulbs in the palmarodistal aspect of the pastern joint. The frog of the foot can also be used as a window to image the DDFT and impar ligament near the flexor surface of the navicular bone. Before imaging, the frog should be trimmed to pliable tissue and the foot soaked in a water bath overnight. Limitations of ultrasound are that the images are restricted to the axial midline, and off-incidence artifacts can confuse image interpretation. If the frog is excessively hard or has deep sulci, poor contact between the frog and transducer may prevent propagation of the ultrasound beam. Variation in cross-sectional area and width of the DDFT and impar ligament both within and between limbs of normal horses also may make image interpretation difficult.

38.14.7 COMPUTED TOMOGRAPHY

CT is the best modality for detecting and evaluating bone pathologies in the cortex or trabecula and can also provide an accurate three-dimensional assessment of soft tissue structures of the foot. Although less expensive than MRI, CT is less versatile. Special contrast studies are needed to evaluate articular cartilage with CT, but not with MRI. One advantage over MRI is that CT can be used to assess accurate needle or scalpel placement for specific treatment options. One disadvantage for CT in horses is the need for general anesthesia and special equipment design to accommodate the horse.

38.14.8 MAGNETIC RESONANCE IMAGING

MRI offers a superior diagnostic tool to image soft tissue structures in the foot. The recent use of MRI in equine lameness has provided valuable insight into the pathologic problems occurring in horses with palmar foot pain. MRI is particularly useful in the recognition of abnormally high signal (fluid) in structures such as the DDFT, IL, and collateral ligaments. MRI also can detect navicular bone edema as well as articular cartilage damage in the navicular region. MRI can be performed under general anesthesia or in the standing horse, depending on the equipment available. In one study of 199 horses with lameness localized to the foot by clinical signs and perineural anesthesia, MRI was found to be superior to nuclear scintigraphy, ultrasound, or radiology in identifying the specific foot structure causing the pain. The most common injury was DDFT desmitis (59%), followed by desmitis of the DIP collateral ligament (31%); 17% of horses had injuries to multiple structures. Only 28% of horses with DDFT or collateral ligament injuries of the DIP joint returned to previous use.[180]

38.15 Etiology

The exact etiology of navicular pain is unclear, but two theories exist. Initially, vascular occlusion of the navicular arteries was believed to result in ischemic necrosis of the navicular bone; however, this theory lacks experimental support. The biomechanical theory suggests that the degenerative changes in the navicular bone result from abnormal forces exerted on the bone and its supporting ligaments. Compression of the navicular bone by the DDFT is an important aspect of this theory. Peak compressive forces of the DDFT on the navicular bone are about 0.77 times body weight during a slow trot and occur at approximately 70% of the stance-phase duration.[177] In addition, the navicular bone suspensory apparatus (IL and CSL) is under excessive tension and possibly

compression when the horse has dorsopalmar hoof imbalance (broken back hoof-pastern axis or long-toe low—heel-hoof conformation). Faulty conformation and improper hoof balance resulting in abnormal biomechanical forces in the navicular area cause pathologic changes in the navicular bone that appear similar to those seen in clinical cases. Pain presumably results from interosseous pressure in the navicular bone or from strain of the supporting soft tissue structures. The biomechanical force applied to the navicular bone depends on hoof conformation and is negatively correlated ($p < 0.05$) to both the angle between the distal phalanx and the ground and the ratio between heel and toe length. Experimental studies seem to support the biomechanical theory.

38.16 Treatment

There are numerous treatment regimens for horses with palmar foot pain, and no one treatment can be recommended in all cases. Factors to consider in determining a treatment plan include prior treatment, duration of clinical signs, structure injured, severity of disease, use of horse, hoof conformation, and shoeing. Treatment options include variable periods of rest, therapeutic trimming and shoeing, antiinflammatory medications, intraarticular therapy, systemic osteoarthritis-modulating drugs, and surgery.

38.16.1 MEDICAL THERAPIES

38.16.1.1 Rest

Taking the horse out of work and confinement to a small area such as a stall and small run allow the horse freedom of movement without being able to run and buck, which could exacerbate the lameness. Controlled exercise at a walk and trot for 15 minutes daily has been shown to increase blood flow to the feet by 15%. Although the duration of the rest period is variable, 3 to 6 weeks will allow soft tissue inflammation to subside and the horse to adjust to changes in trimming and shoeing. If the lameness has resolved after the rest period, a gradual increase in exercise is recommended before returning to normal use. An exception is the horse with an acute ligamentous injury to the navicular suspensory apparatus or distal DDFT injury. These injuries are usually severe and require 6 to 12 months of rest and confinement.

Although rest may be beneficial as part of the treatment regimen, the owner's situation may not allow for a rest period. Other treatments are then required to minimize the pain while allowing the horse to continue working, as often preferred by many professional horsemen.

38.16.1.2 Farriery

Therapeutic trimming and shoeing to reduce biomechanical forces on the navicular/heel area is the cornerstone of treatment for horses with palmar foot pain. Many horses respond to this without further need for medical or surgical therapy. Other horses improve after corrective shoeing but still require additional treatments. Horses with poor hoof conformation or inappropriate shoeing often respond best to corrective shoeing, whereas horses with good farrier management and good hoof conformation may show minimal or no improvement after therapeutic trimming and shoeing. The goals are to (1) restore hoof balance, (2) improve existing problems such as underrun heels, (3) reduce biomechanical forces on the navicular region, and (4) protect injured areas of the hoof. There is no standard shoeing technique for horses with heel/navicular pain; however, observing abnormalities in the hoof and lower-limb conformation and following basic principles can often accomplish these goals. Proper trimming alone may restore correct hoof balance such that special shoes or pads are not necessary; even with proper trimming, however, many horses still require special shoes or pads to achieve the desired hoof conformation. Although many horses benefit greatly

from therapeutic shoeing, some have permanent structural problems that cannot be corrected. The veterinarian, farrier, and owner must work together and consider the horse's hoof shape and hoof wall quality, environment, conformation, use, and severity of disease.

38.16.1.3

Basic Principles for Proper Hoof Balance

The configuration of the hoof capsule reflects the stresses applied to the foot during the previous months. *Hoof balance* refers to both mediolateral and dorsopalmar balance. Dorsopalmar balance refers to proper hoof-pastern alignment. Ideally, when viewed from the side, a line drawn through the central aspect of the first phalanx should bisect the hoof capsule, and the toe angle and heel angle should be parallel to this line. A broken back hoof-pastern axis is common in horses with long-toe low-heel conformation and results in increased stress on the phalangeal joint capsules, navicular suspensory apparatus, and distal DDFT and increases pressure between the navicular bone and DDFT.

Breakover (break-over point) of the foot is the terminal part of locomotion when the heel looses contact with the ground surface, followed by the toe. Tension of the DDFT over the navicular area and flexion of the coffin joint occur during breakover. A low hoof angle or long toe is associated with prolongation of breakover time. A high heel angle reduces breakover, causing a reduction of forces exerted on the caudal structures of the foot and limb (e.g., navicular suspensory apparatus, DDFT, suspensory ligament). Breakover should be made as easy as possible by decreasing toe length.

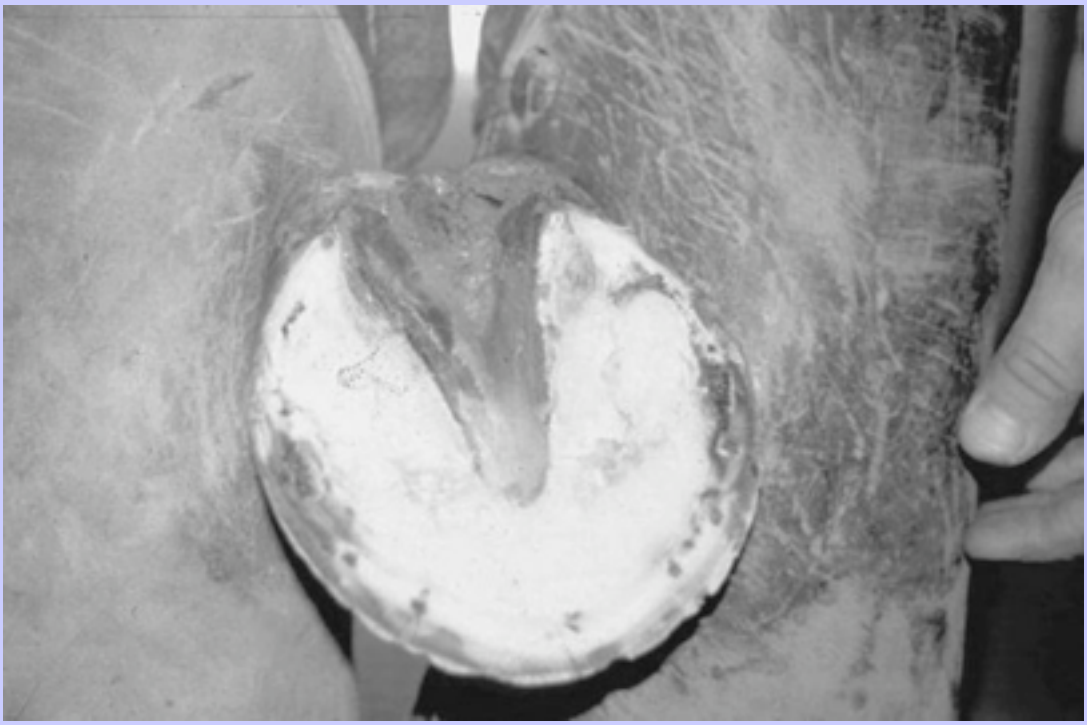
Corrective trimming is often more important but can be more difficult than corrective shoeing. The toe is shortened as much as possible, and the heels are trimmed back to the widest aspect of the frog. One of the most common problems I see is allowing the heels to grow forward, thus decreasing heel support and contributing to dorsopalmar hoof imbalance (Fig. 38-27); the heels lose mechanical strength and often collapse. In addition, the bars of the hoof flatten out and lose support. Proper trimming of the heels back to the widest aspect of the frog increases the functional weight-bearing surface of the foot. The ground surface of the properly trimmed foot has a more rounded appearance (Fig. 38-28). Palmar hoof support is essential for horses with navicular/heel pain. Full-fitting shoes provide more support hoof by increasing the weight-bearing surface. Ideally, the shoe should fit about 1/16 inch wider than the hoof behind the last shoe nail to allow heel expansion. The nails should be placed in a line parallel to the ground approximately 1 inch (2.5 cm) proximal to the shoe, and no nails should be placed behind the widest aspect of the hoof.

Using a wedged shoe or pad to elevate the heels by 2 to 3 degrees after the foot is properly trimmed decreases tension in the DDFT, thus reducing pressure applied to the navicular region. The effect of raising the heels is helped by rolling or rockering the toe to quicken the breakover of the foot. The use of an egg-bar shoe is controversial. Although horses with long-toe, low—heel-hoof conformation may gain caudal foot/heel support from the shoe, egg-bar shoes had no effect on reducing forces between the DDFT and navicular area.

1219 1220

Fig. 38-27 Hoof with the heels allowed to run too far forward. The heels are located at the pointer but should be back at the widest aspect of the frog.

Fig. 38-28 Hoof from Figure 38-27 after trimming the heels back to the widest aspect of the frog. Note the larger, rounded shape to the hoof with increased heel support.



When selecting a particular corrective shoe or shoe/pad combination, the horse's use is an important factor because the desired corrective shoe for the individual hoof conformation may not be suitable for the horse to perform its intended use. A compromise must be made between shoeing for the "ideal" and shoeing for athletic performance, taking into consideration such factors as weight of the shoe, traction, and interference of other limbs. Another important factor is hoof quality. The ideal shoe/pad selected for proper hoof balance may be impossible to apply if the hoof wall is thin or damaged. In these cases, a secondary shoeing regimen is selected that will accomplish similar results until hoof quality improves. Although no standard shoeing technique exists for horses with navicular pain, the following suggestions may be beneficial.

A *rim shoe* or *half-round shoe* has a rounded edge that will enhance breakover. The rim shoe has good traction and is useful in western performance horses, such as roping horses, barrel racers, and cutting horses. The Natural Balance Shoe has a rockered toe and, because of its design, artificially shortens the toe length and enhances breakover. It is made of aluminum or steel; owners of some western performance horses seem to prefer the steel shoe, which is thought to provide better traction than the aluminum shoe.

Acute ligamentous injuries involving the distal aspect of the DDFT or navicular suspensory apparatus require extended periods of rest. During the rest period, application of a 3- to 4-degree wedge pad to the shoeing regimen may decrease tension of these soft tissue structures. Controlled exercise is important in the treatment of these injuries. My group often begins with a 3- to 4-degree pad, depending on the horse's hoof conformation, and gradually decreases the quantity of heel elevation over time.

Different shoeing techniques will accomplish the same goals of easing breakover, supporting the heels, and protecting injured areas of the foot.

38.16.1.4 Nonsteroidal Antiinflammatory Drugs

Phenylbutazone is most common NSAID used in the treatment of navicular/heel pain. It reduces pain by inhibiting the enzyme cyclooxygenase and the subsequent cascade of prostaglandins. It also inhibits platelet aggregation, which may theoretically increase blood flow to the foot. Phenylbutazone can break the pain cycle and allow adjustment to new hoof angles and shoeing changes. The recommended dosage depends on individual horse needs and severity of disease. An initial dosage of 4.4 mg/kg once daily for 5 to 7 days seems appropriate to allow adjustment to shoeing changes. Many horses will require additional treatment during competition. Gastric and right dorsal colon ulceration has been associated with phenylbutazone administration in some horses.

38.16.1.5 Isoxsuprine Hydrochloride

This β-agonist, α-antagonist is a peripheral vasodilator working to increase blood flow to the foot. Its absorption after oral administration in the horse is erratic, and it usefulness is questioned. The recommended dose of isoxsuprine is 0.6 mg/kg twice daily orally for 3 weeks; if no response is seen, the dose is increased to 1.2 mg/kg twice daily for 3 weeks, then once daily for 3 weeks, then every other day for an additional 3 weeks. No adverse drug reactions have been reported. Isoxsuprine's efficacy appears to be horse dependent.

38.16.1.6 Intraarticular Medications

Intraarticular medication of the DIP joint can be beneficial in horses with navicular area pain. Some horses fail to respond adequately to corrective shoeing, rest, and NSAID therapy, or the horse may have responded initially but no longer. If the lameness has been previously localized to the caudal aspect, intraarticular anesthesia of the DIP joint is performed at the recheck examination. If significant improvement is seen in the lameness, the client is offered intraarticular medication as a treatment option. Alternately, if the horse improves after PDN anesthesia in one limb and becomes lame in the opposite limb, anesthesia of the DIP joint is performed. If significant improvement is seen, medication of the DIP joint is offered as an initial treatment option. It is important to remember that DIP joint anesthesia is not specific for navicular area pain, as discussed earlier.

1220
1221

Selection of intraarticular medication varies with the clinician, severity of disease, and client. I usually inject 20 mg of sodium hyaluronate and 6 to 9 mg of triamcinolone (Vetalog), which often alleviates clinical signs of lameness for 6 to 12 weeks. In severe cases of navicular disease, 20 to 40 mg of methylprednisolone acetate (Depo-Medrol) in combination with the sodium hyaluronate may provide a slightly longer duration of effect. Hyaluronate is used for joint lubrication and to increase the hyaluronan content of synovial fluid. Corticosteroids interact with steroid-specific receptors in the cytoplasm of cells and inhibit inflammatory infiltration into the joint and neutrophil function by impairing lysosomal enzymatic release. Corticosteroids also inhibit phospholipase A_2, preventing both cyclooxygenase and lipoxygenase inflammatory pathways.

The two primary reasons not to use intraarticular corticosteroids in horses with joint disease are risk of sepsis and potential adverse effects on articular cartilage and subchondral bone. Using aseptic technique and combining intraarticular antimicrobials with the injection medication should decrease the risk of synovial

infection. I prefer to use 50 to 100 mg of amikacin sulfate for joint injections. To minimize the negative effects of intraarticular corticosteroids, the lowest clinically effective dose is used. Minimal research has been performed in this area, so clinician experience and empirical information are often consulted. Both systemic and intraarticular corticosteroids have been associated with laminitis in horses. DIP joint medication is injected using a 20-gauge sterile needle placed approximately 1 cm dorsal to the hoof capsule on midline, penetrating the extensor tendon while entering the DIP joint. The angle of needle insertion is about 45 degrees from perpendicular to the ground surface. Synovial fluid is usually obtained.

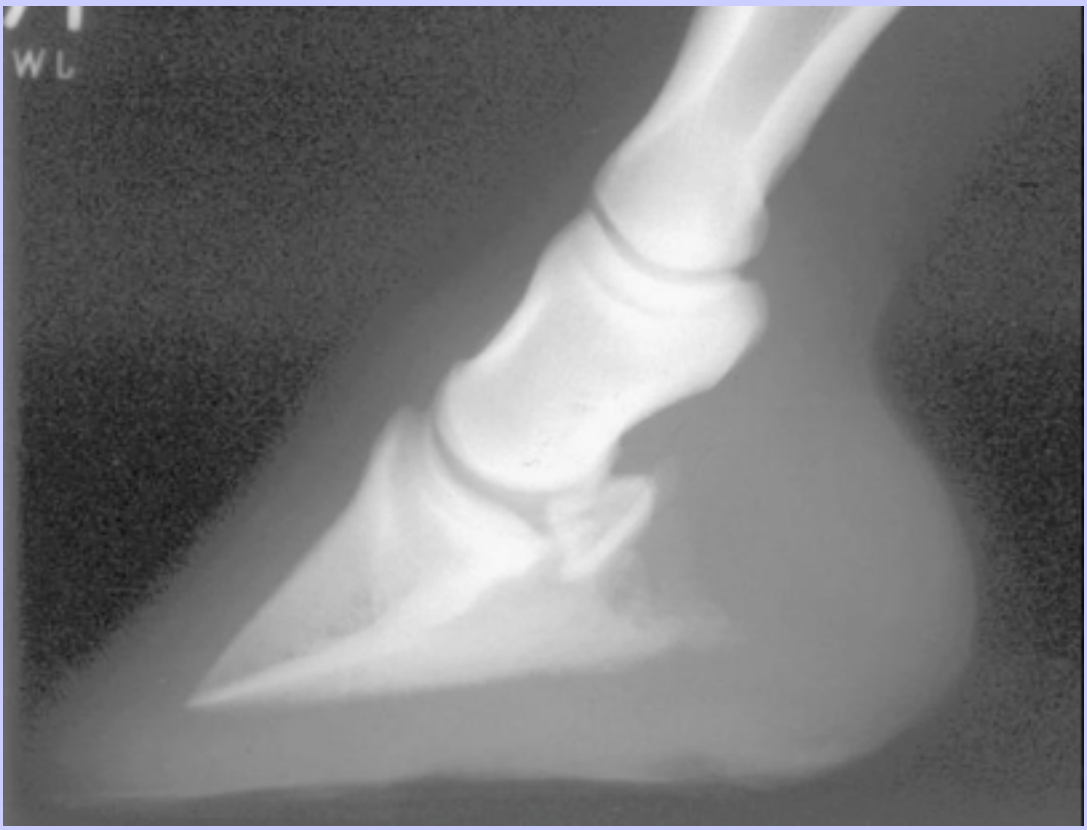
About 30% of horses with pain localized to the navicular area either do not improve or may improve but remain lame after DIP joint anesthesia, which may be associated with different diffusion properties of the local anesthetic versus the intraarticular medication. Drug treatment of the navicular bursa may be beneficial in some of these horses. We recently reported on 25 horses with pain localized to the navicular region that did not respond to corrective shoeing, phenylbutazone, or DIP joint medication.[178] These horses did improve after navicular bursa injection with 40 mg methylprednisolone and remained sound for a mean of 4 months. Most of the 25 horses had moderate to severe radiographic changes involving the navicular bone. Approximately half had an enthesophyte located at the proximal aspect of navicular bone at the attachment of the CSL, possibly indicating chronic CSL desmitis (Fig. 38-29). The technique for navicular bursa injection has been previously described.[178]

38.16.1.7

Systemic Joint-Modulating Drugs

Hyaluronan (HA) is a normal component of synovial fluid and functions as a joint lubricant. It also appears to have some antiinflammatory properties, but the exact mechanism is unknown. Exogenous HA inhibits chemotaxis and phagocytosis of granulocytes and reduces the stimulation of lymphocytes and may decrease the formation of prostaglandin synthesis. The antiinflammatory properties of HA appear to be dose dependent, and HA with a molecular weight greater than 500,000 daltons may be more effective. Systemic HA may be more effective in horses with mild synovitis/capsulitis and less effective on horses with chronic osteoarthritis. The recommended dose is 40 mg HA intravenously once weekly for 3 weeks, then once monthly for maintenance. Some horses with mild navicular pain improve after systemic HA administration, but its use is usually combined with other treatments.

Fig. 38-29 Lateral-to-medial radiograph of foot showing an enthesophyte at the proximal aspect of the navicular bone where the collateral suspensory ligament attaches. Horses with this type of radiographic abnormality usually respond better to medication of the navicular bursa than distal interphalangeal joint medication.



Polysulfated GAGs such as Adequan are referred to as “chondroprotective agents” and are used to prevent, attenuate, or reverse morphologic cartilaginous lesions associated with osteoarthritis. Adequan is made from bovine lung and trachea extracts containing mainly chondroitin sulfate. Previous studies have shown that the antiinflammatory effect of GAGS involves the inhibition of enzymes and cytokines associated with osteoarthritis, such as interleukin interleukin-1 (IL-1, a potent chemotactant agent), metalloproteinases (MMs), and prostaglandin E_2 (PGE_2). Both in vivo and in vitro equine studies have been performed, with conflicting results. More recently, a survey of 1522 equine veterinarians assessing the efficacy of systemic polysulfated GAGS resulted in the subjective conclusion that their use was more effective than HA for treatment of subacute DJD and less effective for acute synovitis. Intramuscular GAG administration was shown to improve lameness in horses diagnosed with navicular syndrome in one double-blind study.[181] The dose was 500 mg IM every 4 days for eight treatments. In our hospital we see many middle-aged western

performance horses with chronic navicular problems. IM Adequan (500 mg) every 1 to 2 weeks subjectively seems to benefit these cases, although no scientific studies support the change in frequency of its use.

The oral chrondromodulatory nutraceutical Cosequin has been evaluated in the treatment of 10 horses with navicular syndrome.[181a] The nutraceutical consisted of 9 g glucosamine, 3 g chondroitin sulfate, and 600 mg manganese ascorbate and was given orally twice daily for 60 days. The clinical impression from the owners was that the horses' lameness showed improvement. Glucosamine has been shown to reduce expression of MMPs and increase the expression of natural inhibitors of MMPs in the joint when studied in vitro. The ability of the horse to absorb these oral nutraceuticals has been questioned, and recent work suggests that doubling the dose currently recommended by the manufacturer improves efficacy of the product, although 4 to 6 weeks of treatment is often needed before a response is seen. I have found that nutraceutical use is variable in horses with navicular area pain, with some showing improvement with daily administration and some showing no effect. Empirically, the benefit of oral nutraceuticals seems inferior to systemic administration of IV hyaluronan or IM Adequan.

1221

1222

38.16.1.8 Other Medical Treatments

Tiludronate, a biphosphonate, is used in human medicine to reduce bone resorption. It has been used to treat navicular area pain in horses with promising results.[182]

Investigated as a treatment for navicular disease in horses, extracorporeal shock wave therapy (ESWT) directs a pressure wave to a specific area of the body to increase osteogenic activity in bones and induce neovascularization at the tendon-bone junction. Human patients have variable duration of analgesic effect after treatment with ESWT. The equine study reported that a single ESWT treatment had no effect on horses with navicular disease.[183]

38.16.2 SURGICAL OPTIONS

38.16.2.1 Palmar Digital Neurectomy

Neurectomy of the palmar digital nerves is occasionally required to allow horses with chronic heel or navicular pain to remain athletically sound. Despite aggressive medical treatment with corrective shoeing, NSAIDs, and intraarticular/intrabursal injections, many horses fail to respond or only improve temporarily, which leaves palmar digital neurectomy as a final treatment option. Before surgery the horse should improve greater than 90% after palmar digital nerve perineural anesthesia. Palmar digital neurectomy resulted in improvement in lameness for a mean of 2 years in one study evaluating 59 horses with navicular disease. Diligent postoperative care is critical to achieve prolonged soundness.[183a] After surgery, a padded pressure bandage is applied to the limb and changed every 4 to 5 days for 2 weeks. The horse remains in a stall for 30 days, followed by 30 days of light riding and resumption of normal activity 60 days after surgery. The limited activity and diligent bandaging after surgery may reduce the inflammatory response and reduce scar tissue formation around the nerve stumps.

38.16.2.2 Navicular Suspensory Desmotomy

This procedure has been recommended for horses with navicular syndrome in the past and applied to a number of cases, without favorable long-term results. Therefore, we are not currently using this procedure and believe it has fallen out of favor as a treatment for horses with navicular pain.

38.16.3 SUMMARY

No single treatment option is suitable for all horses with heel or navicular area pain. Each horse must be evaluated individually to determine which structure in the palmar aspect of the foot is injured, severity of disease, horse and hoof conformation, and horse use and level of performance expectation before a treatment plan can be developed. Many treatment options are available to help these horses to perform.

38.16.4 SPONDYLITIS

SARAH M. REUSS

38.16.4.1 Definitions

Spondylitis is inflammation or infection of the vertebral body. *Diskospondylitis* is an inflammatory lesion that includes the intervertebral disk and its adjacent vertebrae. It is usually confined to one intervertebral joint. Both spondylitis and diskospondylitis are rare in large animals but life threatening. Also called *vertebral osteomyelitis,* spondylitis is most often seen in swine[184] but is also described in horses, cattle,[185] goats,[186] and sheep. Infection is the most likely cause, but an etiologic agent may be difficult to isolate. Neonates are especially at risk for spondylitis. Diskospondylitis in large animals is most often reported in adult horses and cows in the cervical vertebrae.[194–196] Lesions have been identified less frequently in the thoracic,[190,191] lumbar,[192] and sacral[193] regions. The clinical signs and diagnostic approach are similar for spondylitis and diskospondylitis.[190]

38.16.4.2 Clinical Signs and Differential Diagnosis

The earliest signs of spondylitis may include fever, lethargy, stiffness, and localized spinal pain. Soft tissue swelling may be evident with paravertebral abscessation.[194] Muscle atrophy has also been reported in a quarter horse.[191] Because diskospondylitis most often affects the cervical and thoracic vertebrae in horses, neck pain and reluctance to lower the head to graze are common signs. Animals may develop an abnormal stance with one forelimb forward and the other back in order to graze.[190] Vertebral osteomyelitis may progress to spinal cord compression and variable degrees of ataxia, paresis, sensory and proprioceptive deficits, and recumbency. Neurologic signs depend on the vertebral section affected and the amount of spinal cord compression. Clinical signs are usually progressive.

Early clinical signs in ruminants include abnormal behavior, decreased appetite, and weight loss. Difficulty in extending the head and neck ventrally is often the reason for presentation to a veterinarian.[185] Varying degrees of neurologic deficits are reported, from occasional stumbling[185] to tetraparesis[195] and paraplegia.[186]

Differential diagnoses for spinal pain include spondylosis, vertebral fracture, muscle strain, dorsal spinous process impingement, vertebral subluxation, vertebral infarcts, and aberrant parasite migration.[196] Additional differentials for spinal cord ataxia in horses include cervical stenotic myelopathy, equine protozoal myeloencephalopathy, herpes myeloencephalopathy, and neoplasia.

38.16.4.3 Etiology and Pathogenesis

Both spondylitis and diskospondylitis are thought to be septic conditions, although etiologic isolation usually is not successful. Even in cases where bacteria are not isolated, response to antimicrobials may indicate a bacterial pathogenesis.[190] Bacterial infection is more common than fungal infection, and the hematogenous route of infection is the most common. Spondylitis occurs most frequently in neonates. This age predisposition may be caused in part by failure of passive transfer leading to sepsis.[184] In general, spondylitis is often secondary to a preexisting focus of infection elsewhere in the body.[184] Tail-docking wounds,[197] umbilical infections,[184,195] pneumonia,[193] and lung abscesses[184] are possible sources of infection. Septic thrombi embolize into the metaphyseal arteries of the vertebrae, where flow is sluggish and bacteria can colonize.[197] In adults, direct injury to the intervertebral disk or the vertebral endplate may contribute to the formation of diskospondylitis. The injury disrupts the vasculature, increasing susceptibility to infection. Diskospondylitis is also reported to occur secondary to spread of local infection[188] and traumatic injury.[187] Infection results in destruction and remodeling of affected bone. Inflammation of the disk and vertebrae leads to spinal cord compression and the associated neurologic dysfunction. The intervertebral disk may actually prolapse into the spinal canal.[188] The neurologic signs may also be secondary to the infection eroding into the meninges and causing a suppurative meningitis.

Pathogens that have been cultured from adult horses with vertebral osteomyelitis include *Brucella abortus,*[198] *Aspergillus* species, *Streptococcus zooepidemicus,*[184] *Staphylococcus* species,[189,192] and *Mycobacterium bovis*.[199] Vertebral osteomyelitis isolates in foals include *Rhodococcus equi,*[193,194,200] *Streptococcus* species, *Actinobacillus* species, *Eikenella corrodens,*[201] *Escherichia coli*, *Salmonella typhimurium*, *Staphylococcus* species, and *Corynebacterium pseudotuberculosis*.[196] Isolates from cattle with vertebral osteomyelitis include *Aspergillus fumigatus*, *Bacteroides nodosus*, *Clostridium perfringens*, *Streptococcus* species, *Staphylococcus* species,[185] *E. coli,*[197] *Actinomyces pyogenes*, *Fusobacterium necrophorus*, and *Pseudomonas* species.[202] *Staphylococcus* species and *Arcanobacterium (Actinomyces) pyogenes* were cultured from the intervertebral disk of a goat.[186]

1222

1223

38.16.4.4 Diagnosis

Diagnosis is based on clinical signs and imaging modalities. Clinicopathologic findings may include anemia, leukocytosis, neutrophilia, and hyperfibrinogenemia.[184] Hyperproteinemia resulting from hyperglobulinemia may also be seen.[190] Cerebrospinal fluid is usually normal, unless the osteomyelitis has progressed to meningitis. Blood and urine cultures should be obtained but often are not diagnostic.

Radiography is the basis of diagnosis. Radiographic signs of spondylitis include bony proliferation, lysis, sclerosis, and localized soft tissue swelling.[184] Radiographic abnormalities in diskospondylitis include osteolysis of adjacent endplates with surrounding sclerosis and collapsed intervertebral disk space.[192]

Contrast radiography may be used to delineate spinal cord compression.[192] However, radiographic changes may lag 2 to 8 weeks behind clinical signs, compromising early diagnosis.[184] With vague clinical signs, the neuroanatomic location within the vertebral column may be difficult to identify, making targeted radiographs impossible. Nuclear scintigraphy may help to localize the lesion to a specific vertebral section that can then be radiographed.[184] Scintigraphy may also allow earlier detection because of the lag time in radiographic changes. Ciprofloxacin and WBC-labeled scintigraphy may also prove useful in the diagnosis of vertebral osteomyelitis.

Ultrasonography is currently being investigated as a useful imaging modality. Abnormalities include irregular endplates or bone surfaces, wide or narrow disk spaces, vertebral step formation, and associated abscessation or muscle involvement.[192] Transrectal ultrasonography of the lumbar vertebrae may be performed, and transcutaneous studies can image the rest of the vertebral column. Advantages are that ultrasound can be done in the field and can be used for needle-guided aspirates of potentially infectious lesions and as a screening tool to localize lesions.[192] MRI and CT may also be considered as they allow visualization of the endplates, vertebral disk, and spinal cord. CT has been used in a goat to diagnosis diskospondylitis; bone lysis, bone proliferation, mineral opacity in the intervertebral disk, and spinal cord displacement were seen.[186]

38.16.4.5 Treatment

Long-term antimicrobial therapy is indicated for animals with vertebral osteomyelitis. Blood, urine, or tissue culture and sensitivity may be used to guide antimicrobial choices. When this is not possible, broad-spectrum bactericidal antimicrobials should be used. Long-term treatment is necessary and may last 3 to 6 months.[193] NSAIDs can also be used for pain control. In nonresponsive cases, curettage of infected bone may be necessary.[189,193] This also provides an opportunity to collect material for bacterial culture.[193] In horses with instability and spinal cord compression, surgical decompression and stabilization may be indicated.

38.16.4.6 Prognosis

The prognosis for horses with diskospondylitis is guarded to poor. If there are no neurologic deficits and thus presumably no spinal cord compression, the prognosis is more favorable. Early diagnosis and long-term treatment are essential.

38.16.5 SPONDYLOSIS

SARAH M. REUSS

38.16.5.1 Definition

Spondylosis is a degenerative condition of the intervertebral joints. In middle-age and older horses and cattle, the thoracic and lumbar vertebrae are susceptible to chronic, progressive development of enthesophytes within the ventral longitudinal ligament or the ventral margins of the anulus fibrosus. Osteophytes extend across the intervertebral space toward osteophytes on the adjacent vertebrae, resulting in partial bridging where a lucent line persists between the two. Complete bridging *(ankylosis)* can occur, however, without significant loss of intervertebral disk width. A variety of terms are used in veterinary medicine to describe

vertebral enthesophyte formation, including *spondylosis deformans, vertebral osteophytosis,* and *ankylosing spondylosis*.[203]

Spondylosis in horses is most common in mature animals and reportedly in a higher proportion of mares.[204] The most common location in horses is from the tenth to fourteenth thoracic vertebrae. When spondylosis occurs in the thoracic region, the osteophytes are usually ventrolateral, whereas in the lumbar region the osteophytes are more lateral.[205]

Middle-age and older bulls have a higher prevalence of vertebral enthesophytes than other cattle. Bulls used for artificial insemination are especially at risk; in one study, more than 49% of those 8 years and older had spondylosis.[206] In another study, middle-age bulls also had significant pathology, with 21 of 21 dairy bulls age 65 to 90 months having some degree of lumbar osteophytes; 13 had complete ankylosis of at least one intervertebral space.[207]

38.16.5.2 Etiology and Pathogenesis

The exact cause of spondylosis is unknown but is apparently related to altered biomechanics and inflammatory mediators. Some believe that spondylosis is a result of excessive dorsiflexion when the back muscles fatigue.[208] Mechanical stress then leads to tearing of the ventrolateral anulus fibrosus. Chemical mediators act on the periarticular ligaments and joint capsule, leading to metaplastic change. Ossification occurs within the anulus fibrosus and ventral longitudinal ligament, resulting in partial bridging. The cycle may continue until ankylosis is complete and a continuous medullary cavity exists.[203] Partial or complete ankylosis at one site puts more stress on adjacent segments, so there is more active bone remodeling elsewhere in the vertebral column.[205] Secondary DJD of the dorsal articular facets may also develop as a result of altered biomechanics.

The enthesophytes and then the ankylosed vertebral bodies are at higher risk for fracture because of their inability to absorb normal forces. Three percent of bulls at artificial insemination centers have vertebral fractures.[209]

Spondylosis in bulls is not related to force of ejaculatory thrust at service,[210] frequency of semen collection, or high-calcium diets.[209] Despite previous thinking, limited dietary calcium does not reduce the prevalence of spondylosis in bulls.[209]

Nerve roots may be compressed as they exit the intervertebral foramen, and spinal cord compression may occur if the bony proliferation extends dorsally into the vertebral canal. This results in neurologic deficits such as progressive ataxia and paralysis.

38.16.5.3 Clinical Signs and Differential Diagnosis

Spondylosis may be an incidental finding in animals with no history or clinical signs of back pain. However, spondylosis can account for acute, recurrent, and chronic back pain in some animals. Pain is caused by inflammation, impingement, and fracture. Palpation of the spine may be poorly tolerated. Horses may "guard" their vertebral column by using muscle contraction to disallow ventroflexion. Resentment of girthing and mounting may be noticed. Riders may report poor performance, vague lameness, or altered gait.[208] Bulls with spondylosis will have a good appetite and are afebrile, but they may have difficulty rising, be reluctant

to move, and have difficulty mounting.[203] Once present, clinical signs are slowly progressive. Lameness becomes more severe, and neurologic deficits may be seen, when there is nerve root impingement or spinal cord compression. Abnormalities include bilateral proprioceptive deficits of the hindlimbs, with hoof dragging, excessive hindlimb flexion, and incoordination. Hindlimb ataxia can progress to paralysis in some animals, especially older dairy bulls.[207]

Differential diagnoses for spinal pain include muscle strain, vertebral fracture, diskospondylitis, dorsal spinous process impingement, vertebral infarct, and aberrant parasite migration. Additional differentials for cattle with hindlimb neurologic deficits include lymphosarcoma, encephalopathy, progressive degenerative myeloencephalopathy, and downer cow syndrome.[203]

38.16.5.4 Diagnosis

Diagnosis is suggested by clinical signs and, in bulls, a history of reluctance to mount or breed. Palpation of the dorsum may elicit signs of pain. Rectal palpation may reveal ventral osteophytes if they are located on the caudal lumbar vertebrae. A thorough neurologic examination is indicated if there are hindlimb deficits. Cerebrospinal fluid is usually normal.

Standing lateral radiographs are the mainstay of diagnosis. Diagnostic radiographs can be difficult to obtain, however, given the depth of the vertebrae in the thoracolumbar region. If spondylosis is suspected, targeting radiographs to areas of predilection is helpful. Spondylosis in horses is most common in the caudal thoracic vertebrae. In bulls the most common locations are C3-C5, T2-T6, and T11-L5. The largest osteophytes occur in older bulls at the thoracolumbar junction.[206,210] Radiographic changes include smooth bone that blends with the vertebral body and bridges apparently normal intervertebral disks. The clinical significance of radiographic change must also be determined based on history and clinical signs, as spondylosis can be an incidental finding. Nuclear scintigraphy can be useful for determining the activity and potential clinical significance of a lesion based on the radiopharmaceutical uptake. Scintigraphy is also helpful in localizing the lesion for targeted radiography and is an excellent imaging option if diagnostic radiographs cannot be obtained because of size constraints.

38.16.5.5 Treatment and Prognosis

Treatment for clinical spondylosis consists of palliative care. Systemic antiinflammatory drugs, cryotherapy (ice packs, cold hosing), and stall rest are recommended during the acute phase. Once complete fusion occurs, clinical signs should improve. However, if vertebral fractures or neurologic deficits are present, the prognosis is poor.

38.17 LAMINITIS (FOUNDER)

ROBERT L. LINFORD

38.17.1 Definition

Laminitis (“inflammation of the laminae”) is a disease that causes degeneration, necrosis, and inflammation of the dermal and epidermal laminae in the hoof wall of horses and ruminants.

38.17.2 Etiology and Pathogenesis

Because the epidermal laminae suspend the distal phalanx and therefore the body weight of a horse, laminar degeneration destroys the suspension mechanism and permits weight-bearing forces to push the distal phalanx ventrally. Failure of the laminar suspending mechanism causes a painful and potentially crippling lameness. Laminitis is often a sequela of digestive disturbances and other disorders that cause endotoxemia and elaboration of inflammatory mediators. Unless preventive measures are taken, laminitis often occurs after colonic torsion, proximal enteritis, colitis, grain overload, pleuropneumonia, and septic metritis (i.e., postparturient retention of the placenta).[211–215]

In horses, laminitis is sometimes seen following changes in feed, excess intake of cold water after strenuous exercise, grazing on lush spring grasses containing highly available carbohydrates, or persistent feeding of a high-concentrate ration.[211,212] Laminitis may also be precipitated in horses by administration of high levels of corticosteroids,[216] which decrease protein synthesis and potentiate digital vasoconstriction and microthrombosis.[217] Excessive weight bearing in the support limb during severe lameness of the contralateral limb can produce laminitis, as can work on hard ground or extreme exhaustion and dehydration.[211,214,215] A water-soluble toxin in black walnut shavings also has been shown to induce laminitis in horses.[218]

In cattle, laminitis is most often seen immediately after calving in fat heifers that have been fed excess concentrates and kept on concrete surfaces.[219]

38.17.3 Pathophysiology

The pathophysiology of laminitis has not been totally elucidated; however, laminitis is often considered a local manifestation of a variety of disorders that cause a generalized metabolic disturbance. Several factors may produce laminar degeneration. The integrity of the laminar suspending mechanism depends on maintenance of proteins in the cytoskeletal networks, intercellular junctions, and basement membrane of the epidermal laminar cells. This process is energy dependent, and disorders that decrease laminar perfusion or decrease protein synthesis have the potential to initiate laminar degeneration. In addition, laminar degeneration may be initiated by disorders that cause the elaboration of factors cytotoxic to the epidermal laminae, by disorders that activate metalloproteinases, or by disorders that increase the tension on the laminae. Because the laminae and their sustaining vasculature are confined within the rigid hoof wall, factors that cause tissue swelling (e.g., inflammation, edema) can theoretically increase the interstitial tissue pressure beyond critical capillary closing pressure, producing a compartment syndrome and functional ischemia of the corium. Opening of arteriovenous shunts within the corium occurs during carbohydrate-overload laminitis, but such shunting has not conclusively been shown to be the major factor producing laminar degeneration.

Laminitis is often a sequela of diseases producing gram-negative sepsis and endotoxemia, but experimental administration of endotoxin has failed to produce laminitis. However, overingestion of grain or other feeds containing large amounts of highly available carbohydrates is thought to produce endotoxemia and is the most common cause of acute laminitis. Carbohydrate overload results in bacterial overgrowth in the colon, lactic acidosis, decreased colonic pH, colonic mucosal slough, and death of colonic bacteria with concomitant liberation of endotoxin. Degeneration of the colonic mucosa is thought to allow endotoxin to gain access to the portal circulation. The mechanistic link between endotoxemia and laminar degeneration is not totally understood; however, endotoxin that crosses a compromised bowel wall into the portal circulation is removed

by reticuloendothelial cells in the liver, where it likely triggers activation of leukocytes and upregulation of proinflammatory cytokines observed during colitis and grain overload. Hyperimmune serum to gram-negative core antigens has a strong protective effect on horses at high risk of developing laminitis as a result of intestinal crises or carbohydrate overload.[220]

Sequential biopsies of the epidermal laminae and corium during the development of grain-overload laminitis indicated that initial laminar degeneration was most compatible with ischemic or cytotoxic injury, and that a major influx of inflammatory cells, edema, and microthrombosis did not precede laminar degeneration but occurred later and was likely to accelerate the degeneration.[221]

Recent evidence indicates that proinflammatory cytokine expression is increased[222] and leukocytes are activated[223] and begin to emigrate into the perivenular interstitium of the laminar dermis[224,225] during the developmental stages of black walnut extract—induced laminitis. Levels of latent metalloproteinase also increase in the plasma and vascular and perivascular tissues of the dermal laminae during the developmental stages of black walnut extract—induced[226] and carbohydrate-overload laminitis.[227] Matrix metalloproteinases (MMPs) in the laminar region are normally located in the laminar epidermis, where they are thought to play a major role in laminar epidermal remodeling to facilitate hoof wall growth and migration.[228] Early histologic lesions during the developmental stages of laminitis are compatible with excess activation of MMPs and disruption of cell-cell and cell—basement membrane linkages.[221,227] Increased expression of proinflammatory cytokines and activation and emigration of leukocytes during the developmental stage of laminitis may alter the balance between normal levels of activation and inhibition of constitutive MMPs in the laminar epidermis, leading to disruption of the laminar suspending mechanism. Continuous 48-hour application of an ice-water bath to the distal limb is thought to decrease MMP enzyme activity and was recently shown to protect the chilled digit while the contralateral nonchilled digit developed laminitis after carbohydrate overload.[229]

Because perfusion of the most dorsal laminae depends on vessels that course through vascular canals in the distal phalanx, distal migration of the distal phalanx caused by laminar degeneration may compromise laminar perfusion and result in a cycle that intensifies the laminar lesion. It is also theorized that the pain associated with laminar degeneration may cause release of catecholamines that potentiate peripheral vasoconstriction and further diminish laminar perfusion.

38.17.4 Clinical Signs

The signs of acute laminitis are lameness, depression, anorexia, and reluctance to move. Early in the disease, affected animals often paddle or shift weight from one foot to the other. Increased pulsations can be palpated and sometimes visualized in the digital arteries. Hoof-tester examinations reveal sensitivity over the sole at the toe, and tapping on the hoof wall at the toe may elicit pain. Severely affected animals may be unwilling to pick up a forefoot or hindfoot because they are reluctant to bear full weight on the contralateral foot (Obel grade III lameness[230]). The forefeet are usually affected more often and more severely than the hindfeet in horses, and the most dorsal laminae are more severely involved than laminae in the heel regions. Therefore, horses with laminitis typically draw the hindlimbs under the body and place the forelimbs forward to shift weight to the hindquarters and load the heels more than the toes. In ruminants the hindlimbs are most often involved, and affected animals characteristically become recumbent. In severe cases, when laminar degeneration circumferentially involves the foot, a noticeable depression can be palpated along the coronary band. In such cases, exudation is sometimes noted in the coronary region, and the skin may separate from the hoof wall. These signs indicate that the distal phalanx has shifted distally with respect to the hoof wall (i.e., severe rotation

or sinking of the distal phalanx) and suggest a poor prognosis. With dislocation of the distal phalanx, the sole loses its normal cupped appearance and is flat or bulges between the toe and apex of the frog. Pulse and respiratory rates are usually increased, and other clinical signs reflect underlying disease processes.

Signs of chronic laminitis are lameness and abnormal conformation of the foot. The sole is flat or dropped, the white line is widened, and the hoof wall shows signs of uneven growth. Irregular rings of horn, closely spaced at the toe and more widely spaced near the heels, encircle the hoof wall. In ruminants the sole softens and assumes a light-yellow discoloration. Hemorrhages can often be identified in the abaxial white line region, and fissures parallel to the coronary band may be seen in the hoof wall. The signs of subsolar abscessation sometimes mimic those of laminitis; however, abscesses most often involve only one foot and rarely cause anorexia, depression, or increased pulse and respiratory rates.

38.17.5 Clinical Pathology and Radiology

Clinical pathologic findings during the development of acute laminitis most frequently represent alterations associated with underlying disease processes, such as enteritis, colitis, or metritis, and are not pathognomonic for laminitis. During the onset of alimentary laminitis, packed cell volume, total plasma protein, heart rate, respiratory rate, rectal temperature, and blood glucose level are often elevated. Arterial blood pressure is usually elevated in horses but depressed in ruminants.[231] Neutropenia often precedes laminitis caused by disorders that produce endotoxemia; neutrophilia and eosinopenia are often seen later. Changes are thought to reflect compartmental fluid shifts and a stress response consistent with release of glucocorticoids and catecholamines. Horses with chronic severe laminitis, in which euthanasia was deemed necessary, had total WBC counts that were significantly elevated (5,000 to 18,000/μL) compared with control horses and horses that recovered from less severe bouts of laminitis.[232] The persistent neutrophilia was presumably a response to infection and was thought to signify an unfavorable prognosis.

Radiographic examinations should be performed on the affected digits of horses suspected to be developing laminitis. The initial examinations should include lateromedial and 65-degree dorsoproximal-palmarodistal projections. These views should be taken to assess the appearance of the distal phalanx, the soft tissues of the hoof wall and corium, and their relationship. Lateromedial examinations are periodically repeated to check the progression of the disease. Radiographic signs of laminitis include ventral displacement of the extensor process with respect to the coronary groove of the hoof wall, increased distance between the dorsal cortex of the distal phalanx and the surface of the hoof wall, and ventral rotation of the tip of the distal phalanx. Linear radiolucencies are noted interior to the hoof wall in cases where the corium has separated from the epidermal laminae. Increasing degrees of rotation of the distal phalanx and increases in the distance between the dorsal surface of the distal phalanx and the hoof wall indicate progression of the disease (Fig. 38-30).

Fig. 38-30 **A,** Lateromedial radiograph of a normal digit. Two radiopaque markers can be seen. One has been placed on the block below the foot to mark the bearing surface of the wall, and the other marker identifies the location of the dorsal surface of the hoof wall. Notice that the dorsal surface of the hoof wall and the dorsal cortex of the distal phalanx are parallel, and that the distance between them, the soft tissue thickness *(T),* is approximately 25% of the distance from the tip of the distal phalanx to the articulation of the distal phalanx and the navicular bone, that is, the length of the distal phalanx *(L)*. **B,** Lateromedial radiograph of a digit from a horse with severe laminitis. The distal phalanx has dropped ventrally without rotating. This phenomenon is seen in some horses with laminitis. The most consistent radiographic manifestation in such cases is an increased distance between the dorsal cortex of the distal phalanx and the dorsal surface of the hoof wall. The soft tissue thickness, as measured between the dorsal cortex and the dorsal surface of the hoof wall, in this case is 45% the length of the distal phalanx. The soft tissue thickness is normally less than 28% of the distal phalanx length for thoroughbred racehorses. **C,** Lateromedial radiograph of a digit from a horse with severe laminitis. Note the linear radiolucency dorsal to the distal phalanx *(arrowhead)*. This lucency indicates a separation between the corium and primary epidermal laminae and marks the inner aspect of the hoof wall *(arrows)*. The dorsal cortex of the distal phalanx is rotated approximately 14 degrees with respect to the inner surface of the hoof wall. Note that the dorsal and inner surfaces of the hoof wall are not parallel. This is the result of rasping along the distal portion of the dorsal surface of the hoof wall. The soft tissue thickness in this case is greatly increased to almost 42% of the distal phalanx length.

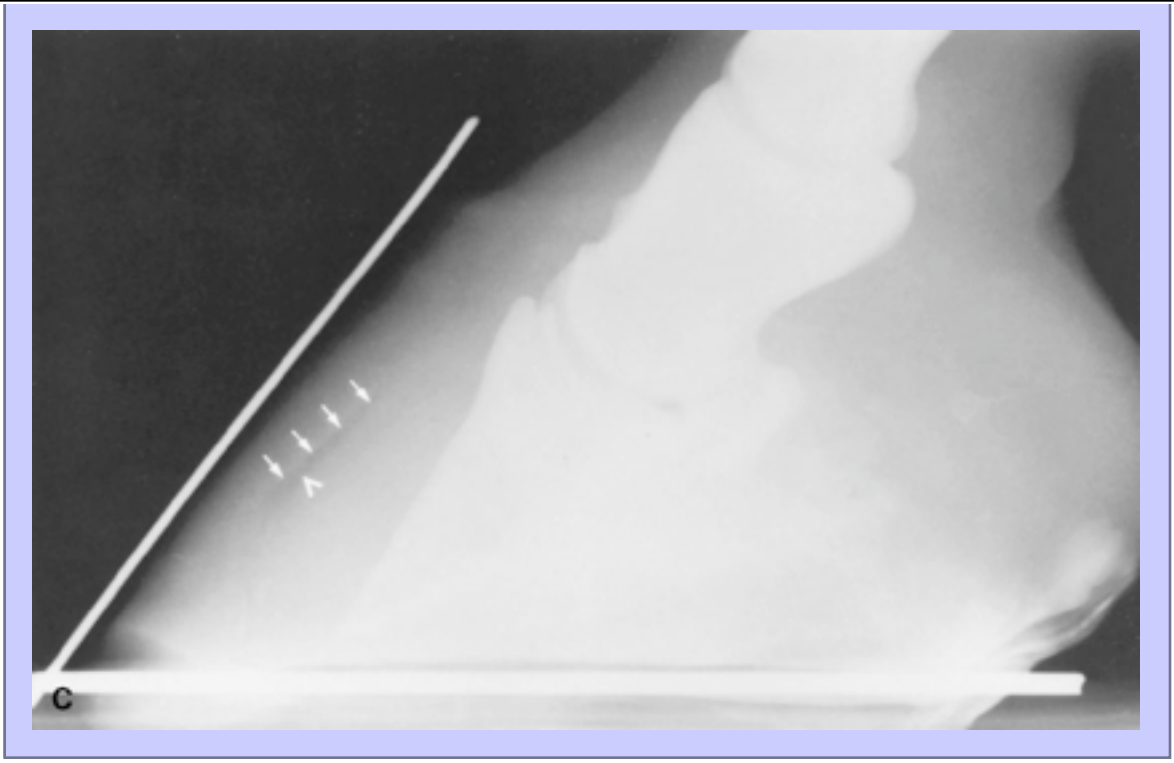
L
A
B



Because variations in technique affect subsequent radiographic distance and angle measurements, it is essential to standardize the radiographic procedure to detect small changes between examinations. For the lateromedial radiograph, the foot is cleaned and placed on a wooden block approximately 3 inches (7.5 cm) thick. A radiopaque marker can be embedded in the dorsal surface of the block and along the dorsal surface of the hoof wall to aid in determining the amount of rotation of the distal phalanx. However, marking the surface of the dorsal hoof wall is generally not necessary when digital radiographs are available. A small section of metal wire or a groove can be placed in the proximodorsal hoof wall as a reference for measuring vertical displacement of the distal phalanx in repeated radiographs, and a thumbtack is often useful in marking the apex of the frog for radiographic and anatomic correlation before therapeutic shoeing.

The radiographic beam should be perpendicular to a sagittal plane through the digit and should be centered midway between the toe and heels, about 1 inch (2 to 3 cm) above the bearing surface of the wall. The radiographic cassette should be parallel to the sagittal plane through the digit and should be placed as close to the foot as possible. Using a consistent technique and performing the examination in a standardized manner permit straight lateral radiographs to be produced and allow accurate quantification of radiographic parameters so that subtle changes may be identified early.

One of the earliest and most reliable radiographic signs of laminar deformity is an increase in distance between the dorsal surface of the hoof wall and the dorsal cortex of the distal phalanx. When the laminar suspending mechanism fails, weight-bearing forces cause the distal phalanx to displace distally or rotate away from the dorsal hoof wall, and the increased distance between the structures can be quantitated radiographically. Increased distance between the dorsal hoof surface and the dorsal cortex of the distal phalanx was significantly associated with increased laminar deformity during laminitis.[221]

A *laminar index* measurement has been developed to reduce the need to account for differences in radiographic magnification when comparing radiographs from different hospitals, from different breeds, or from different sizes of horses. It is useful to calculate the laminar index adjacent to the proximal and distal aspects of the dorsal cortex of the distal phalanx. The *proximal* laminar measurement is taken as the shortest distance between the linear portion of the dorsal cortex of the distal phalanx and the dorsal surface of the hoof wall immediately distal to the extensor process of the distal phalanx; the *distal* laminar measurement is taken in the same way, 5 to 6 mm proximal to the tip of the distal phalanx (see Fig. 38-30). The proximal and distal measurements are used to produce proximal and distal laminar indices by expressing them as a proportion of the length of the palmar cortex of the distal phalanx, as measured from the tip of the distal phalanx to its articulation with the navicular bone. The palmar cortex measurement serves as an index of foot size, and if the proximal or distal measurements spanning the laminae are increased in relation to the length of the palmar cortex, laminar deformity has occurred. Both the proximal and the distal laminar index measurements should be less than 30% of the palmar cortex length. The index measurements ranged between 20% and 28% for nonlame racing thoroughbreds[221,233] and were greater than 30% in horses with laminitis,[234] ranging up to 50% to 55% in those with severe laminar deformity.[221] If the proximal and distal laminar indices are almost equal and both are greater than 30%, the distal phalanx has sunk in relation to the hoof capsule, without rotation (see Fig. 38-30). When both indices are greater than 30% and the distal index is greater than the proximal index, sinking and rotation of the distal phalanx have both occurred. Sinking generally indicates that laminar degeneration involves more than the dorsal wall laminae and carries a worse prognosis than for horses with rotation alone.

38.17.6 Epidemiology

A survey of the risk factors associated with laminitis indicated that intact mares and stallions were at greater risk of developing laminitis than geldings. Ponies also accounted for a significantly greater number of laminitis cases than expected based on their proportion of the caseload. The peak incidence of new cases also corresponded with growth of lush spring grasses, suggesting that ingestion of large quantities of fresh grass is also a significant risk factor for pastured horses.[235]

Other risk factors include diseases that cause excess weight bearing or trauma in the digit and diseases that produce endotoxemia. Persistent feeding of a high-concentrate ration, stabling on concrete surfaces, long van trips, and exposure to or ingestion of black walnut wood products are also thought to be associated with an increased risk of laminitis. In addition, horses that previously had laminitis are at greater risk than other horses.

38.17.7 Necropsy Findings

Peracute cases may have total degeneration of the secondary epidermal laminae, which causes a separation between the primary epidermal laminae of the hoof wall and the collagen fibers of the corium. Abscessation may occur in the necrotic laminae or subsolar tissues. The distal phalanx may sink or may be rotated ventrally with respect to the hoof capsule, and the tip may penetrate the sole (Fig. 38-31). Severe cases are accompanied by fractures of the solar margin, osteomyelitis, or severe resorption of the distal phalanx. The necropsy findings generally demonstrate a variable degree of elongation of the epidermal laminae, which depends on the severity and duration of the problem (Fig. 38-32).

Fig. 38-31 **A,** Midsagittal section from the foot of a horse with a normal digit. Note the distance between the dorsal surface of the dorsal cortex of the distal phalanx *(open arrows)* and the inner surface of the hoof wall *(arrows)*. The dorsal surface of the hoof wall and dorsal cortex of the distal phalanx are parallel. Compare with Figure 38-30, *A*. **B,** Midsagittal section from the foot of a horse with severe laminitis, a "sinker." Note the increased distance between the dorsal surface of the dorsal cortex of the distal phalanx *(open arrows)* and the inner surface of the hoof wall *(arrows)*. Also note that the distal phalanx has not rotated with respect to the hoof wall. Compare with Figure 38-30, *B*. **C,** Midsagittal section from the foot of a horse with severe laminitis. There is approximately an 18-degree rotation of the distal phalanx, and its tip has penetrated the sole *(curved arrow)*. Note the increased distance between the dorsal surface of the dorsal cortex of the distal phalanx *(open arrows)* and the inner surface of the hoof wall *(arrows)*. Compare with Figure 38–30, *C*.

38.17.8 Treatment

Treatment of animals developing acute laminitis should be considered an emergency. Laminar degeneration is underway by the time clinical signs of lameness appear, and even a few hours of delay in treatment can mean the difference between success and failure. Therapy should be initiated before development of clinical signs when the untreated animal is at high risk of developing laminitis (e.g., animals that recently ingested a large quantity of grain; mares with retention of placenta; horses with enteritis, colitis, or strangulating intestinal lesions).

General principles of therapy are aimed at eliminating the cause, promoting digital circulation, reducing tension on the laminae, reducing platelet activation and coagulation, and administering NSAIDs and free-radical scavenging agents to minimize digital inflammation and necrosis and to relieve pain.

38.17.9 ELIMINATING CAUSE

A laxative or purgative should be administered to animals that have ingested a large quantity of grain. In such cases, 3 to 4 L of mineral oil is usually given through a nasogastric tube. Intravenous administration of balanced electrolyte solution is indicated for horses with laminitis resulting from exhaustion, dehydration, and hypovolemia. Retained placentas should be treated appropriately if the placenta has not been expelled within 3 hours after parturition in mares. Antiendotoxin hyperimmune serum may be indicated for horses at risk of developing endotoxemia as a result of colon torsion, toxic diarrhea, toxic proximal enteritis, septic metritis, grain overload, or other disorders.

38.17.10 ADMINISTERING NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Phenylbutazone is recommended, and at the onset of the syndrome it may be given once at a dose of up to 8.8 mg/kg intravenously (IV), usually followed by 4.4 mg/kg orally (PO) twice daily for several days. The dose should be tapered to 2.2 mg/kg (PO twice daily) as soon as possible. For horses with endotoxemia, flunixin meglumine* (1.1 mg/kg IV twice daily) is often used instead of phenylbutazone. Dimethyl sulfoxide (DMSO) also may be given daily (0.2 to 1.0 g/kg) for 2 or 3 days. To administer it IV in a 450-kg horse, 250 mL of the 90% solution is mixed in 3 L of balanced electrolyte solution and given slowly. DMSO should be diluted to a concentration that is less than 20% to avoid hemolysis when given IV. The use of aspirin (10 mg/kg IV or PO once daily) is sometimes advocated for its antiinflammatory and antiplatelet activities. Corticosteroids and adrenocorticotropic hormone (ACTH) are contraindicated because they decrease protein synthesis and may potentiate peripheral vasoconstriction and microthrombosis.

* Banamine, Schering Plough Animal Health, Union, NJ.

38.17.11 REDUCING TENSION ON LAMINAE

The force related to suspending the weight of the horse by the attachment between the hoof wall and the distal phalanx is likely to be a major factor producing laminar deformity in horses with laminitis. Reduction of laminar tension may be achieved by focusing the forces of weight bearing more on the frog and sole and reducing the amount of weight taken by the hoof wall. This can be accomplished by using frog support bandages or shoes, sole casts, or sand stalls. Elevation of the heel with an 18-degree wedge has been advocated to reduce the pull of the deep flexor tendon and decrease the tension on the laminae.[236] This elevation can be achieved with a plastic-cuff shoe* that is bandaged or glued to the hoof wall and used with a frog support cushion† and an 18-degree heel wedge. An elevated-heel hoof cast has also been advocated and shown to reduce strain on the dorsal hoof wall laminae.[237]

For horses with severe acute laminitis, do not lower the heel in the acute stage, and avoid shoes that require the horse to bear full weight on one foot for a prolonged period while the shoe is being nailed on the other. Avoid using shoes that increase laminar tension by transferring more weight-bearing forces to the hoof wall. A plastic-cuff heel-wedge shoe can be temporarily taped to the hoof with minimal trauma and effort. If it makes the horse more comfortable, the shoe can be glued in place. Frog support shoes continue to put pressure on the frog when the horse is recumbent and may predispose to subsolar necrosis. Frog support bandages or Lilly Pads‡ provide satisfactory support and avoid the complications associated with shoeing. The toe should be dubbed off to decrease the lever arm effect that a long toe has on prying the wall away from the distal phalanx during breakover.

Affected horses should be encouraged to lie down to reduce laminar tension. This goal can usually be accomplished with sedation. The stall should be heavily bedded with straw and pine chip shavings to a depth of 1 to 2 feet (30 to 60 cm) for comfort and to reduce the risk of pressure sores.

38.17.12 PROMOTING DIGITAL CIRCULATION

Walking with frog supports in soft ground for 5 to 10 minutes every 3 to 4 hours is beneficial for nonlame horses during the developmental stages of laminitis. It may increase the amount of laminar deformity when used in horses with lameness or in nonlame horses that have a depression at the coronary band indicating that laminar degeneration has already begun. Alpha-adrenergic blocking drugs such as acetylpromazine, phenoxybenzamine, and prazosin have also been advocated to decrease peripheral vasoconstriction and promote digital circulation. Acetylpromazine (0.02 to 0.04 mg/kg intramuscularly four times daily) may be given for its theoretic effect on digital circulation and for the sedative effect that encourages the horse to lie down and reduce laminar tension. Before lameness develops, heparin may be administered (40 to 100 units/kg subcutaneously two or three times daily) to provide laminitis prophylaxis by attenuating potential microthrombosis. This therapy significantly reduced the proportion of horses developing laminitis after proximal enteritis when given before onset of lameness.[238]

38.17.13 OTHER TREATMENTS

Antibiotics may be indicated in severe cases to reduce the risk of secondary sepsis in the foot. Methionine (20 to 60 mg/kg PO once daily) and biotin (0.03 to 0.2 mg/kg PO once daily) have been used for their effect on keratinization. Recently, a continuous (48-hour) ice-water bath has been advocated to chill the distal limbs of horses at risk for developing laminitis. Other methods of cooling the distal limbs include using bandages that continuously circulate ice water and simply adding crushed ice to a rectal sleeve and tying it to the pastern to chill the dorsal hoof wall, replacing it several times daily as needed. Rectal sleeves with ice are economical, well tolerated by horses, and simple to use, but are likely to be less effective than continuous ice-water baths or bandages.

Fig. 38-32 **A,** Section of a healthy foot. The section was cut parallel to the coronary band, midway between the coronary band and the bearing surface of the hoof wall *(inset, S)*. The length of the epidermal laminae *(L)* is approximately 33% of the thickness of the hoof wall *(W)* in normal horses. The distance between the dorsal cortex of the distal phalanx *(open arrows)* and the inner surface of the hoof wall *(arrows)* is normally less than 75% of the thickness of the hoof wall. **B,** Foot section, cut in a manner similar to that of *A,* from a foot of a horse with moderate laminitis. Note the increased length of the epidermal laminae *(L)*. The increase in epidermal laminar length has allowed the distance between the dorsal cortex of the distal phalanx *(open arrows)* and the inner surface of the hoof wall *(arrows)* to become almost as large as the thickness of the hoof wall *(W)*. **C**, Foot section, cut in a manner similar to that of *A,* from a foot of a horse with severe laminitis. Note the marked increase in length of the epidermal lamina *(L)*. The distance between the dorsal cortex of the distal phalanx *(open arrows)* and the inner surface of the hoof wall *(arrows)* is abnormally increased to almost three times the thickness of the hoof wall *(W)*.

38.17.14 Prognosis

Owners should be advised that it is often difficult to arrive at an accurate prognosis for up to 6 weeks after the original insult. Redden[239] has suggested the following general guidelines regarding prognosis.

Horses that become sound within 24 to 48 hours of the onset of treatment, remain sound, demonstrate no radiographic changes, and have no palpable increased pulsation of the digital arteries after cessation of all medications for 5 days have a good prognosis. They should be given 10 additional days of stall rest, after which they can be vanned or put back to regular work.

Horses that develop 2 to 5 degrees of rotation or a laminar index measurement of 30% to 35% within the first 30 days of the onset but then become sound, remain sound, and show no further radiographic progression after an additional 45 days without treatment have a good prognosis. They may resume light exercise, but they should not be shipped long distances for several months, and they should be considered to have an increased risk of recurrence.

Horses that develop 5 to 10 degrees of rotation in the first 6 weeks but then have no further radiographic progression should receive an additional 90 days of stall rest. If they remain sound without medication, they may resume light exercise with caution after they have been turned to pasture for an additional 12 months. Such horses will not return to their previous level of performance and are not suited for racing or endurance, but they may function as pleasure horses.

Horses that develop 10 to 15 degrees of rotation within the first 4 to 6 weeks have a poor prognosis. The tip of the distal phalanx often penetrates the sole. Necrosis of the dermal and epidermal laminae and subsolar tissues usually occurs. Drainage often is noted at the coronary band or heels and is an indication of subcapsular abscessation. Gas or fluid pockets may develop between the hoof wall and the dorsal surface of the distal phalanx. Such cases require drainage and debridement of the necrotic tissue, which may be accomplished through an anterior hoof wall resection. If the keratinized sole is underrun, it is thinned enough to be elevated off the underrun areas so that necrotic debris can be curetted and the area flushed with antiseptic solution. Daily bandage changes and antiseptic flushing or soaking are required. If all necrotic subsolar tissue can be accessed without removing the keratinized sole, a thin layer of keratinized tissue should be left in place. Horses with a thin layer of keratinized sole are usually more comfortable than those in which the sole has been completely removed. Leaving a thin layer of keratinized tissue reduces the potential for exuberant granulation and seems to increase the rate of reepithelialization across granulating wounds in the sole.

Horses with this degree of laminitis require several months of stall rest and will be chronically crippled, at best. They will require several thousand dollars of care and bandaging just to stabilize the foot. The foot usually remains chronically painful, and, if so, euthanasia is justified on humane grounds. Tenotomy of the deep digital flexor tendon is beneficial in these cases. It seems to permit such severely affected horses to become more comfortable, enhances reepithelialization of defects in the sole, and permits the dorsal hoof wall to grow better.

Horses that have circumferential laminar necrosis in which the distal phalanx drops 2 cm or rotates 15 to 20 degrees with respect to the hoof capsule, or horses that develop a laminar index greater than 50% within the first 4 to 6 weeks of onset, carry a grave prognosis.

38.17.14.1 Prevention and Control

Prevention should be aimed at controlling as many risk factors as possible. Unrestricted grazing on lush spring grasses should be avoided, especially in areas where horses have developed laminitis in preceding years, and especially for horses with a history of laminitis. Horses should not be allowed to have unrestricted access to grain or concentrates, nor should they be fed a ration that primarily consists of concentrates. Factors that cause gastrointestinal upsets should be avoided; for example, changes in the ration should be made slowly, and overheated horses should not be allowed to engorge on cold water. Retained placenta in the mare should be treated within 3 hours after parturition.

Preventive measures should be instituted before clinical signs develop for horses that are at high risk of developing laminitis from conditions such as metritis, torsion of the colon, pleuropneumonia, proximal enteritis, or colitis. Preventive therapy should include frequent walking, frog support bandages and stabling on soft surfaces, cooling the distal limb, and administration of NSAIDs and antiendotoxin hyperimmune serum.

38.17.15 FLUOROSIS

JOHN MAAS

38.17.15.1 Definition and Etiology

Ingestion of excessive fluoride by cattle, sheep, and horses can result in toxicosis. Acute fluoride toxicosis is relatively rare and is the result of accidental massive ingestion of fluoride compounds such as sodium fluoride or sodium fluorosilicate. Signs of acute fluoride toxicosis include restlessness, stiffness, anorexia, agalactia, salivation, vomiting or regurgitation, urinary incontinence, diarrhea, clonic convulsions, hyperemia, weakness, severe depression, and cardiac failure. Necrosis of the gastrointestinal mucosa and high concentrations of fluoride in plasma and urine are present in acute fluoride toxicosis. Chronic fluoride toxicosis is most often referred to as *fluorosis,* a general term that includes osteofluorosis and dental fluorosis. The most common sources of excess fluorides in the diet are (1) water with a naturally high fluoride content, (2) forages contaminated with fluorides from nearby (upwind) industrial plants (e.g., phosphate-processing plants, aluminum plants, smelters), (3) mineral (nondefluorinated rock phosphorus) and feed supplements with excessive fluoride content, (4) forages contaminated by soil or water (particularly sprinkler irrigation water) with a high fluoride content, and (5) volcanic activity, which can deposit fluoride-containing ash on soil, plants, or in water used for agriculture.

1231

1232

38.17.15.2 Clinical Signs, Differential Diagnosis, and Patho-physiology

Clinical signs of fluorosis are usually first recognized as either dental fluorosis or osteofluorosis. Developing teeth are very sensitive to the ingestion of excess fluorides. The deciduous teeth rarely show signs of dental fluorosis because a partial placental barrier to the accumulation of fluorides appears to be present in the fetus. During tooth development, excess fluorides cause ameloblasts to reduce in size prematurely and the enamel epithelium to form an irregular matrix. This matrix does not calcify normally, producing defects in the mature teeth. Cattle are susceptible to dental fluorosis during enamel matrix formation, from approximately 6 months to 3 years of age. Excess fluoride intake after 3 years of age does not result in the typical fluoride-induced dental lesions. Changes in incisor teeth are observed most frequently and include chalkiness,

mottling (striations or patches in enamel), hypoplasia (defective enamel), and hypocalcification. Clinical lesions can be graded from normal to excessive.[240] Factors that influence dental fluorosis include the amount of fluoride ingested, the animal's age, the duration and consistency (intermittent vs. continuous) of exposure to fluoride, and the source and chemical form of fluoride ingested. Although diagnostically useful, dental lesions should not be used as the sole criterion to determine the degree of fluorosis.

Fluoride accumulation in bone occurs over a prolonged time; *osteofluorosis* can eventually develop if excessive fluoride is ingested. In cattle the first palpable lesions occur on the medial surface of the proximal third of the metatarsal bones. Later, lesions can be palpated on the mandible, metacarpal bones, and ribs. Radiographically, osteofluorotic bones are thickened with a chalky, roughened, and irregular periosteal surface.

The presence of osteoporosis, osteosclerosis, hyperostosis, osteophytosis, or osteomalacia depends on the amount of fluoride ingested and the duration of exposure to fluorides. The articular surfaces are not involved in osteofluorosis and can be used to differentiate osteofluorosis from osteomyelitis, osteoarthritis, and septic arthritis. The osseous lesions eventually cause intermittent lameness and stiffness, which may affect feed intake, body condition, milk production, and reproduction. Severe dental fluorosis causes reduced feed intake and efficiency, and affected animals are sometimes reluctant to drink cold water.

Table 38-3 Fluoride Concentration in Bones of Dairy Cattle Fed Various Levels of Sodium Fluoride

	Fluoride in Bone (ppm; Dry, Fat-Free Basis)		
Fluoride in Feed (ppm, Dry Basis)	**2 years**	**4 years**	**6 years**
0-15 (Normal conditions)	401-714	706-1138	653-1221
15-30 (No adverse effects)	714-1605	1138-2379	1221-2794
30-40 (Borderline fluorosis)	1605-2130	2379-3138	2794-3788
40-60 (Moderate fluorosis)	2130-3027	3138-4504	3788-5622
60-109 (Severe fluorosis)	3027-4206	4504-6620	5622-8676

38.17.15.3 Clinical Pathology and Diagnosis

Diagnosis of fluorosis is difficult and complicated by many factors that affect fluoride intake and deposition. Fluorosis may be suspected by history, clinical signs, and physical examination. Radiographic findings of bone disease without evidence of joint involvement are highly suggestive of fluorosis in the live animal. The fluoride concentration in the urine of cattle may help to approximate recent fluoride exposure. The diagnostic value of urine fluoride analysis increases as the duration of excess fluoride ingestion increases. Normal cattle have a urine fluoride concentration of about 2 to 6 parts per million (ppm). Cattle exhibiting moderate fluorosis have urine fluoride concentrations of about 15 to 20 ppm. Cattle with urine fluoride concentrations

of 40 ppm or greater or a urinary fluoride/creatinine ratio of 0.025:1 or greater could be suspected of ingesting a diet with a fluoride concentration of 60 ppm or greater.[240,241] The concentration of fluoride in bone is quite helpful in the diagnosis of fluorosis (Table 38-3). Fluoride content in cancellous bone (e.g., rib, pelvis) is greater than in cortical bone. In addition, fluoride concentrations may vary in different areas of the same bone.

Fluoride concentration of bone is usually expressed as ppm (mg/kg) of dry, fat-free bone; however, some bone samples are ashed before fluoride determination. Therefore, it is critical to note precisely which bone was sampled, how it was prepared, and what part of the bone was analyzed. The metatarsus and metacarpus are typically analyzed for fluoride content. For all practical purposes, fluoride concentration is equal in either of these bones from the same patient.[170] Using sawdust from a longitudinal section of bovine metatarsus (dividing the bone into lateral and medial halves or dorsal and palmar halves) yields virtually the same fluoride concentration as the whole bone.[242] The fluoride concentration of the fourteenth coccygeal vertebrae (ash basis) is approximately twice that of the metacarpus (dry, fat-free weight basis).[243] This is a practical tool for clinical diagnosis.

Analysis of dietary fluoride is a valuable adjunct to the diagnosis of fluorosis. The upper safe limit of fluoride in water for livestock is 2 mg/L (ppm).[244,245] This safe limit may not protect against fluorosis in all field situations because of the large number of variables involved in the pathogenesis of fluorosis. Table 38-4 lists the long-term dietary tolerances for cattle. Under field conditions, the clinician must consider all possible sources of fluoride ingestion in evaluating total intake. In addition, because fluoride intake may be intermittent, a low dietary intake at one time may not necessarily eliminate a diagnosis of fluorosis.

38.17.15.4 Treatment and Prognosis

No specific treatment is known for ruminants with severe fluorosis, and the prognosis is poor for cattle lame from extensive bony lesions. Animals removed from the offending diet or water may lose 50% of the fluoride from bone within 2 to 5 years;[246] however, severe dental damage is irreversible.

1232

1233

Table 38-4 Long-Term Tolerances of Dietary Fluoride for Cattle

Animal	Dietary Fluoride (ppm, Dry Basis)
Dairy or beef heifers	30-40
Mature dairy cattle	40
Mature beef cattle	40-50
Fattening cattle	100

38.17.15.5 Prevention and Control

Prevention involves avoiding feeds, water, and supplements with excessive fluoride concentrations. Feeding aluminum sulfate at 0.5% of the total diet reduces bone fluoride storage by 30% to 40%. However, additional phosphorus must be supplied in the diet, or osteoporosis and possibly spontaneous fractures may occur. Aluminum chloride or calcium aluminate also can be fed to cattle to reduce fluoride absorption. Calcium carbonate added to soils high in fluorides aids in reducing fluoride in forages. Cereal grains do not

accumulate fluorides and thus can be helpful in reducing overall fluoride consumption. In circumstances of high fluoride concentrations in water, use of flood irrigation rather than sprinkler irrigation decreases the fluoride content of crops such as alfalfa hay.

38.17.16 HYPERTROPHIC OSTEOPATHY

M. KEITH CHAFFIN

38.17.16.1 Definition and Etiology

Hypertrophic osteopathy (HO), also known as *Marie's disease,* is an uncommon condition in horses and is characterized by symmetric proliferation of connective tissue and subperiosteal bone along the diaphyses and metaphyses of the bones of the distal extremities.[247–249] The skeletal manifestations of HO are usually secondary to a primary underlying disorder elsewhere in the horse's body, often involving a space-occupying mass.[247–250] Most often, intrathoracic disorders are the primary cause;[248] intraabdominal and intracranial lesions have been less frequently associated with HO.[248,250,251] In addition to horses, HO has also been described in humans, dogs, cats, cattle, deer, and fowl. In humans the term *hypertrophic osteoarthropathy* is used because the articular surfaces are usually affected; in animals, however, HO apparently does not frequently affect the articular surfaces.[247–249]

In the horse, HO has been associated with a number of primary intrathoracic disorders, including mycobacterial pneumonia,[248,252] lung abscess,[247,248] suppurative pneumonia,[247,248,253] granulomatous pneumonia, systemic granulomatous disease,[248,249] fibrosing pneumonia,[254] primary and metastatic lung neoplasia,[253,255–258] pulmonary infarction,[259] rib fracture,[260] pleural adhesion,[248] and pericarditis.[261] Reported primary extrathoracic disorders associated with HO include ovarian neoplasia,[262–264] pituitary adenoma,[251] and gastric squamous cell carcinoma.[250] There is one report of HO in a mare that was thought to be associated with pregnancy; signs of HO developed during three different gestational periods and regressed each time after parturition.[253] In occasional cases, HO may develop in the absence of an identifiable underlying disorder.[248]

38.17.16.2 Pathophysiology

The pathophysiology of HO is not completely understood. Initially, blood flow to the distal limbs is increased, followed by proliferation of connective tissue, then bony proliferation along the inner aspect of the periosteum.[247–249] The periosteal proliferation results in the bony enlargements seen clinically. The link between the primary lesion and the skeletal abnormalities is poorly understood. Proposed explanations include hormonal abnormalities, hypoxia, arteriovenous shunting, and neurologic mechanisms.[247–249] No single theory offers a completely satisfactory explanation.

Horses of any age or breed and either gender can be affected with HO. Some evidence suggests that HO may be more common in male horses and large-breed horses.[248] Ponies, donkeys, cattle, and sheep can also be affected.[253,256] The condition appears to be most common in mature horses.[253]

38.17.16.3 Clinical Signs

Common clinical signs of HO include lameness, stiff gait, and reluctance to move or trot.[247–249] Firm bony enlargements are present on the distal extremities. In some cases, there may be soft tissue swelling or edema adjacent to the bony enlargements. In some horses the limb swelling is warm and painful to palpation, whereas in others the swelling is cold and painless.[248] Pain can frequently be elicited by forced flexion of the major joints. Bony enlargements are usually bilateral and symmetric and often affect the cranial, lateral, and medial aspects of the affected bones.[247,248] All four limbs are usually affected.[248] The metacarpal and metatarsal bones are most often affected; other sites that can be affected include the phalanges, carpus, tarsus, radius, and tibia, as well as the maxilla, mandible, and nasal bones.[248]

Affected horses may or may not show signs related to the primary underlying disorder, such as cough, fever, weight loss, ventral edema, tachypnea, or colic.[248] Clinicopathologic features are highly variable and depend on the underlying primary disease process. Generally, there is increased serum activity of alkaline phosphatase, associated with increased osteoblastic activity at the sites of periosteal proliferation.[248,249]

Radiographically, the bony enlargements are characterized by periosteal proliferative, new bone formation of the diaphysis and metaphysis of affected bones.[248] The periosteal reaction often exhibits an irregular, palisade pattern of osteophyte formation.[247,248] The bony reaction may extend to the chondrosynovial junctions; the articular surfaces are usually not affected.[249] In a few cases, nuclear scintigraphy revealed focal areas of intense uptake of radiopharmaceutical at the sites of bony enlargement.[247,261]

38.17.16.4 Treatment and Prognosis

The prognosis for horses with HO is guarded and depends on the underlying disorder. In one study, 71% of horses with HO were euthanized.[248] Gradually progressive limb swelling and pain is the typical clinical course in most affected horses for which an underlying cause is either not identified or effectively managed. Thus, management of HO should be directed at identification and treatment of the underlying primary disorder, if possible. Common methods to aid in identification of the underlying disease include hematology, serum chemistries, fibrinogen, thoracic radiography, thoracic and abdominal ultrasonography, abdominocentesis, thoracocentesis, gastroscopy, and rectal examination. Successful management of the primary underlying disorder has resulted in partial or complete regression of the skeletal disease in a limited number of equine cases.[247,248,262] Regression of HO is characterized by a decrease in limb swelling and lameness, and a return to athletic performance is possible if bony lesions are not advanced.[247] In a few idiopathic cases in which an underlying disorder was not identified, bony reactions decreased with rest and phenylbutazone therapy.[248]

38.17.17 FESCUE FOOT

ERIC W. DAVIS

38.17.17.1

Definition and Etiology

Fescue foot is a toxicosis of cattle grazing pastures that contain tall fescue grass (*Festuca arundinaceae* Schreb). The condition is characterized by lameness, particularly of the rear limbs, progressing to dry gangrene of the feet and lower legs. The end of the tail and the ear tips occasionally may be affected.

Fescue pastures also cause three other syndromes. “Summer slump” is characterized by reduced gain and milk production, dull hair coat, and poor heat tolerance. Abdominal fat necrosis also has been reported in cattle on fescue pasture.[265] Equine reproductive problems, including prolonged gestation and agalactia, as a result of grazing tall fescue late in gestations have also been described.[266]

The earliest description of “fescue foot” appeared in 1949 in Australia. It has been reported in Europe, New Zealand, and the United States, particularly in the Southeast. The etiologic agents in fescue have not been definitely established, although several toxins have been identified.[265,267–271] Chemicals produced by the grass itself (e.g., loline, perloline, several organic acids) could be toxic agents contributing to fescue foot and other syndromes, but mycotoxins produced by endophytic fungi, which infect tall fescue, are generally accepted as being the most important agents. The endophytic fungus of tall fescue, *Acremonium coenophialum* (formerly *Epichloe typhina*), produces ergovaline, ergonine, ergosine, and lysergamide.[265,267,271] All these toxins are capable of producing vasoconstriction similar to that caused by ingestion of the ergot fungus *Claviceps purpurea*. In fact, the symptoms of fescue foot are identical to gangrenous ergotism. Pastures not infected with *Acremonium* do not produce any of the symptoms of fescue toxicosis in animals.[271]

Environmental factors also play a role in the development of fescue foot. Although the disease can occur over a range of seasons, symptoms usually occur during colder months. Another factor is the level of pasture fertilization. High levels of nitrogen in soil, regardless of the form applied, increase pasture toxicity. Certain strains of fescue, particularly Kj-31, seem to be more toxic.[272] Finally, because the endophyte imparts a selective advantage on the infected plant by increasing growth rate and disease resistance, the number of toxic plants in a pasture increases. The infestation rate of the fescue endophyte is high; more than half the forage samples from states in which fescue foot occurs are infected with *A. coenophialum*.[273]

38.17.17.2

Clinical Signs and Differential Diagnosis

Clinical signs of fescue foot usually begin as hindlimb lameness. Affected cattle also are underweight and have a dull, “rough” hair coat. The feet and pasterns become cold to palpation, and the coronary bands become reddened and swollen. Hair may be rubbed from the pastern area with the fingers, and limb edema may be present. As the condition progresses, the classic signs of fescue foot appear, including a sharp line of demarcation at the level of the pastern or fetlock, distal to which the skin becomes dry and gangrenous and eventually sloughs. The tips of the ears and tail also may necrose. Affected animals lose condition initially and eventually are unable to stand or to walk. Susceptibility to the toxin in animals on a given pasture seems to vary considerably. Generally, morbidity is low, although 20% to 30% of the herd may be affected in some circumstances.[274]

The diagnosis is made on the basis of characteristic signs and gross lesions, as well as the presence of tall fescue in the pasture. As mentioned, gangrenous ergotism is identical clinically, except that it occurs in the

presence of the easily recognizable “ergot” fungus *C. purpurea,* which grows on rye grass. Similarly, chronic selenium toxicosis (“alkali disease”) mimics fescue foot, except that this disease does not occur on fescue pastures, and affected animals have elevated tissue selenium concentrations. Both ergot and selenium poisoning affect animals other than cattle, whereas fescue foot has been described only in the bovine.

Early in the course of the disease, mechanical foot injury, foot rot, or laminitis can resemble fescue foot, especially because only a few animals in a herd are affected. Close inspection of the foot, however, reveals lesions that are typical of these diseases. Necrosis as a result of freezing may be difficult to distinguish from fescue toxicosis because both occur at the same time of year.

38.17.17.3 Pathophysiology

Pastures that contain tall fescue infected with *A. coenophialum* produce toxins responsible for vasoconstriction. Peripheral vasoconstriction causes blood stasis, endothelial damage, and thrombosis in peripheral vessels. As a result of impaired circulation, tissues of the distal extremities become ischemic and gangrenous. By decreasing peripheral circulation, cold ambient temperatures exacerbate the condition.

38.17.17.4 Necropsy Findings

At necropsy the principal finding is a characteristic line of demarcation between normal and gangrenous tissues. Generalized loss of condition also is found because of the animal's inability to ambulate and eat. Vascular thrombosis and necrosis of the tissues of the lower limbs are found microscopically.

38.17.17.5 Treatment and Prognosis

When animals with fescue foot are recognized early in the disease course, they should be removed from pasture as soon as possible. Antibiotic treatment to prevent bacterial invasion of injured skin and hooves is valuable; recovery can occur in 2 weeks. Once the extremities have necrosed, however, treatment is unsuccessful and euthanasia is recommended.

38.17.17.6 Control

Unlike *C. purpurea,* which grows only on the seed head of grasses, the toxins causing fescue foot are contained in the leaves and stems. As a result, mowing contaminated pastures is not an effective control measure. Growing strains of tall fescue with low toxicity, mixed with legume forage plants, seems to be the best management technique for controlling fescue foot. In cold weather, feeding hay to cattle when the pasture contains tall fescue decreases the ingestion of toxins.

38.17.18 INTERDIGITAL NECROBACILLOSIS (FOOT ROT) IN CATTLE

JARED J. JANKE

38.17.18.1 Definition and Etiology

Interdigital necrobacillosis is an infectious disease of cattle that is a leading cause of lameness in feedlots and confinement dairies. The condition can affect cattle at any age, although most cases are in mature or weaned

animals. Sporadic cases are encountered with pastured beef and dairy animals. A variety of names have been used to describe this condition, including "foul-in-the-foot," foot rot, and interdigital phlegmon (phlegmona interdigitalis). The condition is characterized by inflammation and tissue necrosis of the soft tissues of the interdigital space.[275] Deep structures (e.g., tendons, ligaments, synovium, bone) may be involved in severe cases. *Fusobacterium necrophorum,* a gram-negative anaerobic rod, has classically been considered the etiologic agent associated with foot rot; however, multiple anaerobic organisms are likely to be synergistically involved. Typical foot rot lesions could be induced 5 days after inoculation of the interdigital cleft with *F. necrophorum* alone.[276] *Prevotella melaninogenicus* and more recently *Porphyromonas levii* (both previously classified in the genus *Bacteroides*) have been reported to play an important role.[275] The presence of *Dichelobacter nodosus*, the agent associated with contagious foot rot in small ruminants and interdigital dermatitis in cattle, may facilitate penetration of the skin with *F. necrophorum*. Wet, unsanitary conditions and rough environmental flooring are important factors in precipitating infection.

1234

1235

38.17.18.2

Clinical Signs

Early in the course of foot rot, symmetric swelling and heat of the interdigital space are noted, progressing to the coronary band and possibly extending proximally to the level of the fetlock. The claws begin to spread as a result of severe cellulitis, leaving a widened interdigital space. Soft tissue swelling leads to necrosis and fissure formation within a few days,[277] starting at the dorsal interdigital space and spreading toward the heels. The edematous skin margins protrude and roll outward (Fig. 38-33). Exudation and pseudomembrane formation are seen, but significant purulent drainage is not evident. A characteristic foul odor accompanies the necrotic lesion. Acute and progressive lameness in one limb is typical, with the hindlimbs more frequently involved than the forelimbs.[278,279] Septic synovitis, osteomyelitis, or tendon involvement is more likely to result in non-weight-bearing lameness and limb carriage. Mild to moderate elevation of the body temperature (39.4° C to 40° C [103° F to 104° F]) may be recorded. The associated pain leads to reduced ambulation, feed intake, and milk production as well as weight gain. Affected animals may spend a significant amount of time lying down, predisposing them to injury from herdmates. Systemic effects of inflammation and infection can result in reduced fertility in breeding bulls. Differential diagnoses for lameness of the foot include trauma, interdigital dermatitis, verrucose dermatitis, and laminitis.[280]

A severe form of foot rot described more recently is peracute in onset and refractory to conventional treatments.[278,281] Severe interdigital swelling is noted in multiple limbs and most often in the hindlimbs. The condition is rapidly progressive, leading to recumbency and a rapid extension to deeper structures. Euthanasia may be warranted on animal welfare grounds.[282] Penicillin/sulfonamide-resistant *F. necrophorum* has been isolated from several cases.[281] Concurrent infection with bovine viral diarrhea (BVD) virus and the resultant immunosuppression have been suggested as an etiology.[283]

Fig. 38-33 Foot rot in a mature Angus cow. The interdigital skin is cracked and swollen. *Photo courtesy of Dr. Kevin Washburn, Texas A&M University, College of Veterinary Medicine & Biomedical Sciences, Large Animal Clinical Sciences.*

38.17.18.3 Clinical Pathology

Laboratory analysis of blood is not typically done, although a normal or an inflammatory leukogram may be encountered. Collection of samples for microbial culture is seldom done because of the ability to diagnose the condition through typical clinical findings. Lesional swabs or biopsy samples may be submitted for bacterial culture. A mixed population of environmental and fecal contaminants is likely; however, isolation of *F. necrophorum* and other anaerobes suggests true foot rot. Microscopic evaluation of biopsy samples may identify spirochetes, although this is not a consistent finding.

38.17.18.4 Pathogenesis

The mechanisms of interdigital necrobacillosis are complex and incompletely understood. Compromise of the skin barrier is critical for invasion of the offending pathogens. Chronic exposure of feet to wet and dirty conditions leads to softening and maceration of the skin. Exposure to sharp gravel and stones, excessive stubble, irregular concrete, and other forms of mechanical trauma can result in significant abrasions and damage to the interdigital skin, particularly in wet environments. The combination of these two factors can result in penetration of the offending pathogens and resultant infection. Initial microbial flora may reduce

tissue oxygen tension, allowing anaerobes an ideal environment to proliferate.[280,284] Once the organisms colonize the subcutaneous tissues, multiple mechanisms likely promote growth and evasion of the host defense systems.

The two subspecies of *F. necrophorum* currently recognized are biotypes A and B. Biotype A appears to be more virulent and is more frequently isolated.[285,286] Others have described differentiation of virulent strains by colony morphology,[287] and PCR differentiation of strains is available.[288] Although *F. necrophorum* is also a human pathogen, differences apparently exist between human and animal strains.[285] *F. necrophorum* is a normal inhabitant of the gastrointestinal tract of ruminants, although isolation from feces is generally rare.[285,289] Oral administration of some antimicrobials has been shown to increase fecal shedding of *F. necrophorum*.[290] The increased number of organisms in exudate from necrotic lesions may provide an important source of transmission to other animals. Major virulence factors associated with this organism are a high—molecular-weight leukotoxin and lipopolysaccharide (LPS).[291,292] The leukotoxin is cytotoxic to ruminant neutrophils and, when combined with LPS, may protect the organism from phagocytosis.[285]

Recent findings suggest that *P. levii* did not stimulate a significant chemotactic response in bovine macrophages in vitro, and suppression of phagocytosis occurred when the organism was present in low numbers.[275] These properties of *P. levii* may facilitate a local tissue environment that allows other anaerobic organisms, including *F. necrophorum,* to colonize and evade host defense mechanisms.

38.17.18.5 Epidemiology

Interdigital necrobacillosis has been recognized worldwide for centuries.[293] Wet and humid climates predispose to disease, and foot rot has been associated with rainy seasons.[284,294] The risk of disease is higher in management systems that expose animals to traumatizing ground underfoot, such as concrete confinement 1235
with water and excrement accumulation, irrigated pastures, muddy lots, high stocking densities, and stony 1236
walkways. As noted, cattle of any age are susceptible, but mature animals account for most cases. *Bos indicus* breeds appear to have a lower incidence of foot rot than *Bos taurus*, and Jersey cattle may be overrepresented in the dairy breeds.[294]

38.17.18.6 Necropsy Findings

Postmortem examination is rarely performed. Characterization of the lesions reveals subcutaneous and soft tissue necrosis, with suppurative inflammation of the foot. In severe cases, evidence of osteomyelitis, tenosynovitis, and septic arthritis may be identified.

38.17.18.7 Treatment and Prevention

Most animals are responsive to parenteral antimicrobial therapy. Local treatment (e.g., topical preparations, wound care, bandaging) is probably not necessary for minor cases identified early, although local therapy may reduce the number of infectious organisms spread to the environment.[284] The organisms are typically susceptible to a variety of antimicrobials.[278] Procaine G penicillin (22,000 to 44,000 IU/kg intramuscularly [IM] once or twice daily) has been used successfully when infection is detected early.[284] These dosages of penicillin are considered extralabel, and the clinician must take appropriate steps to ensure adequate meat-

and milk-withdrawal periods. Currently, a number of drugs have been approved for the treatment of foot rot in the United States.[278,282] Amoxicillin (6.6 to 11 mg/kg IM or subcutaneously [SC] for 5 days), oxytetracyline (10 mg/kg IM or SC), sulfadimethoxine (55 mg/kg PO or IV loading, then 27.5 mg/kg PO or IV daily for 5 days), erythromycin (2.2 to 4.4 mg/kg IM daily for 3 to 5 days), ceftiofur (1.1 to 2.2 mg/kg SC daily for 3 to 5 days), tylosin (18 mg/kg IM daily for up to 5 days), sulfamethazine (30 g/100 kg PO, repeated in 72 hours), and florfenicol (40 mg/kg SC once).[278,280,282,284]

Early recognition and treatment can produce clinical improvement in 2 to 4 days.[278] The antimicrobial of choice can be tailored to suit the needs of the farm in terms of withdrawal times, number of treatments, route of administration, and familiarity with the product. Investigators found that 5 mg/kg of extralabel tilmicosin SC at the onset of lameness resulted in a 74% cure rate, significantly higher than with placebo.[295] Antiinflammatory therapy, including flunixin meglumine or aspirin, may reduce fever and provide analgesia, resulting in improved appetite and ambulation.[282]

When topical therapy is warranted, cleaning the wound and curettage of the necrotic tissue are beneficial. A variety of topical antimicrobial or astringent preparations can be placed under a foot bandage. The main objectives of bandaging are to keep the wound clean and prevent further contamination from fecal organisms for several days. Moving treated animals to clean, dry areas is recommended.[280] Dressing the foot to prevent further spreading of the digits helps to protect the interdigital space. Foot bandaging may also reduce the amount of exudate from infected feet, which could infect herdmates.[284]

Spontaneous recovery is possible, although the risk of complications is increased, and recovery may take several weeks.[280] Animals with significant deep structure involvement may require prolonged therapy and repeated wound management. Animals with evidence of septic arthritis of the distal joints or other synovial structures may require amputation of the digit to allow drainage. Claw amputation has been described.[282,296]

Metaphylaxis, or the mass treatment of animals, may be warranted in some circumstances. Methods to mass-treat animals involve topical treatment in the form of footbaths or the addition of feed-grade antimicrobials and supplements to diets. It is prudent to inform owners that no feed additives are currently approved for the prevention or treatment of foot rot.[297] Extralabel use of feed additives, as governed by the Animal Medicinal Drug Use Clarification Act, is strictly prohibited.[278,297] The only antimicrobials approved for nonenteric disease as food additives are chlortetracycline and oxytetracycline.[297] Ethylenediamine dihydriodide (EDDI) has been used to reduce the severity and incidence of foot rot,[298] although high doses are toxic in cattle. EDDI use for this purpose is prohibited, based on the present regulation of feed additives.[278,297]

Footbaths are an appealing alternative for many producers, but proper use is important. Contact time and efficacious ingredients are sometimes difficult to ensure. Footbath additives often are rapidly contaminated with organic material, eventually leading to inactivation.[297] Antibacterial agents and astringents have been traditionally used, including 3% formalin, 2% copper sulfate, oxytetracycline, and lincomycin-spectinomycin formulations. Dry footbaths have also been reported and include 10% copper sulfate and slaked lime.[280] Practitioners must check state and local laws, which may prevent the use of some substances that could cause environmental contamination and might be unsafe for handlers.

Vaccination against *F. necrophorum* has been available for some time, but firm evidence of its efficacy in peer-reviewed publications is limited.[278] One study evaluating the incidence and severity of hepatic

abscesses and foot rot suggested a positive response to vaccination of feedlot cattle compared with controls, although the significance was evident only in the free-choice forage program. The same positive result was not evident when the analysis included all cattle, particularly the limit-fed grain program. The benefit of vaccination may not be able to overcome the challenge of diets that promote rumenitis.[299]

38.17.19 INFECTIOUS FOOT ROT IN SHEEP AND GOATS

JARED J. JANKE

38.17.19.1 Definition and Etiology

Infectious foot rot is a highly contagious foot disease of sheep and goats and is the leading cause of infectious lameness in these species.[300,301] The essential pathogen is the anaerobic bacterium *Dichelobacter nodosus*.[301–310] Synergistic activity with other microbes, primarily *Fusobacterium necrophorum,* plays an important role in the pathogenesis.[300,303,304] Equally important are the roles that environmental moisture and climate contribute to the transmission from animal to animal.[300,303–305,309] The infection has been reported in a variety of species, including cattle, horses, pigs, deer, and mouflon, but is generally considered a sheep and goat—specific disease.[307]

38.17.19.2 Epidemiology

Foot rot accounts for significant economic losses in sheep-producing countries[302,304,306,307] and has often resulted in government control programs.[301,305] Reduced body and fleece weight and increased costs of management, treatment, and culling make control of this disease important. Infectious foot rot is found worldwide wherever sheep and goats are reared, although it is primarily a problem in warm and humid climates.[300,303–305,309] Sheep raised on improved pastures in arid regions may also develop the disease.[304] Prolonged periods of moisture are required to facilitate transmission; short periods of heavy rainfall do not lead to significant increases in clinical disease.[300,303,304] Consistent temperatures greater than 10° C (50° F) are considered favorable for transmission.[300] Incidence rates are likely to correspond with the seasons that favor these conditions and may vary between geographic regions. Using pastures with ground cover that promotes trauma to the foot is likely to increase the risk of disease. The natural herding behavior of sheep and goats is likely to propagate the spread of the organism within a flock. Traditionally, routine hoof trimming was thought to reduce the incidence by improving general foot health; however, others have not made this association and have actually proposed trimming as a risk factor.[300,301,304,309]

1236

1237

Sheep are the primary species of concern, although other ruminants can be infected. An association with increased severity in lambs from aged ewes has been suggested.[304] The merino breed appears to be the most susceptible, whereas British breeds demonstrate less severity.[303,304] Clinical disease is more often diagnosed in adults, although lambs may also be affected. Age and breed have been identified as risk factors, with an increase in incidence with age. Breed genetics and heritability may play important roles in resistance to disease, and reducing matings from chronically infected sheep may be an important step in propagating less susceptible breeding lines.[301,304] Introduction of the organism to a naive flock is almost exclusively by the addition of asymptomatic, chronic carrier animals, which may harbor the organism on their feet for years.[303,304] Animals exposed to pastures or housing facilities immediately contaminated by infected feet are at

risk of contracting the organism. *D. nodosus* is an obligate parasite of hooves and survives only a short time in the environment, but it may remain viable for up to 2 weeks in favorable conditions.[303,304]

38.17.19.3 Pathogenesis and Clinical Signs

The interdigital skin is typically an adequate barrier to infection. In prolonged wet conditions, however, the skin becomes macerated and weakened. Initially, *F. necrophorum* invades the skin and superficial soft tissues, resulting in *ovine interdigital dermatitis* (OID). This organism may produce a local tissue environment that promotes invasion of *D. nodosus*. These two organisms work synergistically to allow *F. necrophorum* to invade into deeper tissues and allow bacterial proteases produced by *D. nodosus* eventually to cause horn separation. Both organisms are essential for true foot rot to occur.[300] The lesion associated with foot rot is characterized as exudative inflammation and necrosis of the epidermal tissues of the foot.[307] A characteristic foul odor is almost always present.[303,304] Both claws of multiple limbs are typically involved. The interdigital skin becomes moist and swollen, and the soft horn is pale, pitted, and may be separated from the skin.[303]

Disease associated with *D. nodosus* infection is highly dependent on the virulence of the organism, resistance of the animal, and environmental conditions. All these factors are extremely variable; relatively low virulent strains in wet conditions may contribute to more severe disease than a highly virulent strain in dry weather. Virulence is associated with the keratinolytic ability of a strain and occurrence of type IV fimbriae.[300,302,304–307] The fimbrial subunit gene, fimA, appears to be essential for virulence.[304] Heat-stable protease production is characteristic of virulent strains.

Infectious foot rot is categorized into two clinical syndromes, benign or virulent, based on clinical severity and the ability to transmit through the flock. Some have included a third, intermediate syndrome for cases that clinically are more involved than the benign form but are not associated with the appreciable production losses that occur with the virulent form.[300] Foot rot accounted for a 10% decrease in body weight and wool production in one report.[307] It may be difficult to define clearly each case early in the disease process; what appears to be benign may be the early onset of the more virulent form. Benign foot rot may progress to separation of the soft horn from the underlying hard horn; however, it does not progress beyond this point. Virulent foot rot is characterized by severe interdigital lesions with separation of the soft and hard horn from the sensitive laminae. The separation begins at the axial surfaces of the heels and progresses in a dorsolateral direction.[303,304] Underrunning of the sole occurs, and in the most severe cases, the entire hoof may be sloughed. When confronting acute, multiple-limb lameness in several animals in a flock, a practitioner should strongly consider virulent foot rot.

The spread from animal to animal is generally rapid, and multiple stages of the infection are present within the flock. Inspection of the flock is indicated to categorize the severity of infection. In some flocks, only a small portion needs to be examined to determine the classification of disease, whereas evaluation of the majority of the flock is required in other cases. If uncertainty exists, 2 weeks is usually adequate to allow lesions to progress to a stage that will accurately allow classification of the clinical syndrome.[300] Affected animals may graze on their knees to relieve the foot pain or may remain recumbent in severe cases. Systemic signs of infection may include fever, anorexia, and weight loss.[303] Complications of the foot wounds include blowfly strike and secondary bacterial infection.[303,304] Although susceptible, the clinical course in goats is

often less severe. Interdigital dermatitis is a more prominent clinical finding than separation of the horn in this species.[303]

Differential diagnoses for foot rot include traumatic injury, laminitis, foot abscess, OID, and *contagious ovine digital dermatitis* (CODD). The presence of interdigital dermatitis increases the risk of the development of foot rot, and the prevalence may be high in the early stages of foot rot infection. It may be impossible to distinguish clinically between interdigital dermatitis and benign foot rot.[300]

Identified in the United Kingdom in the mid-1990s, CODD was initially thought to be a severe form of virulent foot rot. Clinically, the disease shows similarity to infectious foot rot, although initial involvement of the interdigital space is usually absent with CODD. Ulcerative lesions involving haired skin adjacent to the coronet are more common. This condition responds poorly to traditional foot rot treatment strategies. The complete pathogenesis of CODD is unclear, but one report isolated *D. nodosus* in 74% and a spirochete in 70% of affected feet. The spirochete was from the genus *Treponema,* which has been associated with similar lesions in cattle.[310]

38.17.19.4 Clinical Pathology, Diagnostic Tests, and Necropsy Findings

Samples collected by swabs or lesion material can be submitted for anaerobic microbial culture. The mixed bacterial population present and the fastidious growth of *D. nodosus* make isolation difficult and time-consuming.[302,307] Collection of samples in anaerobic transport containers and rapid submission to the laboratory are required. One report found that *D. nodosus* could not be isolated from field samples if they remained longer than 3 hours in transport.[302] Routine growth media found in most laboratories is usually not sufficient to grow this organism, and selective media and techniques are helpful in isolating this microbe.[302] Microscopic examination of *D. nodosus* organisms by Gram stain reveals large, barbell-shaped, gram-negative rods.[303,307] Some investigators have reported colony morphology and correlation with virulence, but others have been unable to make this correlation.[302]

1237

1238

Biochemical testing for elastase activity and thermal stability of bacterial proteases has been used to differentiate benign from virulent strains. Thermostability of bacterial proteases can be measured by the gelatin gel test,[304,305,307] although false-positive results have been reported.[305] Advanced molecular techniques, including PCR and DNA sequencing, have recently become available for detecting gene sequences that encode for virulence, particularly fimA.[302,305,306] These advanced techniques have expanded the classification and number of strains and serotypes identified[302,305,306] and allow a rapid and sensitive diagnostic tool for use in control programs.[304] Serum antibody detection using an ELISA is available, but its specificity may be lacking.[304] Serology may be helpful in determining flock involvement. Infectious foot rot is usually diagnosed on clinical findings, and postmortem examination is not typically necessary.

38.17.19.5 Treatment and Prevention

Once *D. nodosus* infection is identified in a flock, treatment to control and potentially eradicate the organism should be initiated. Eradication may not be possible in all flocks, and the severity of disease, management practices, strain virulence, and environmental factors undoubtedly play a critical role. Separation of animals confirmed to have lesions is likely to reduce the transmission to uninfected flockmates; however, this may not be possible under some management strategies. When possible, planning pasture rotation to allow 2-week

dormancy periods enables producers to have infection-free zones. Improving pastures to prevent areas of standing water, excrement, and mud will theoretically reduce the potential for transmission. Routine flock foot trimming has been a mainstay in the prevention of foot rot, although supportive clinical data are lacking.[300,301] Regions having consistent problems with foot rot have discontinued this practice because of the lack of evidence and the increase in time and labor.[301] However, judicious foot trimming for the treatment of foot rot is probably beneficial on an individual basis and when topical treatments are employed.[301,303,304] Meticulous paring of the hoof may be necessary if the disease has produced overgrown and misshapen feet that promote hiding places for *D. nodosus*. Disinfection of knives and shears between each animal is important to reduce iatrogenic transmission. Treatment is typically more successful during the dry periods of the year, when transmission is reduced.

Medical treatment methods for foot rot include topical therapy, including footbaths, topical medications, and parenteral antimicrobials. Although bandaging individual feet may increase the contact time of medications and reduce the spread of infectious material, this is not practical and does not allow the foot to dry. Topical 5% oxytetracycline tincture has been used successfully.[304] Chemicals used in footbath solutions include 5% copper sulfate, 3% to 5% formalin, and 10% zinc sulfate.[300,303,304] When used properly, these agents are usually highly effective, but caution must be used with each chemical to prevent adverse effects. All these agents are potentially toxic to varying degrees if ingested, and copper sulfate will stain the fleece. Comparison of formalin and zinc sulfate in footbath preparations yields similar results.[304] Formalin is more resistant to contamination by organic material, but higher concentration and frequent application are extremely irritating to the skin. Additionally, considerable human health concerns and government regulations may prevent the use of formalin in some flocks. Efficacy and improved safety make zinc sulfate an ideal agent for use in footbaths. Improved chemical penetration of the hoof can be achieved when the surfactant sodium lauryl sulfate is combined with the footbath solution, reducing the need for foot trimming before treatment. Use of footbaths requires facilities and construction (6 to 12 m [20 to 40 ft] long) that ensure all feet on each animal are treated. The ideal contact time has not been established in clinical studies, but brief walk-through or soaking for up to 1 hour has been shown to be successful.[300] The frequency of treatment is also not clearly defined and may be dictated by the contact time. Because of its irritating properties, formalin should not be used more than once a week.[304] Although the response is likely multifactorial, cure rates of 50% to 80% have been reported with foot bathing. Separate footbaths for infected and noninfected animals reduce the risk of inadvertent transmission. Washing the feet by walking animals through a plain-water bath and allowing the feet to dry 2 hours before and at least 1 hour after treatment is ideal.[300] Once treated, the groups should be immediately moved to clean, dry pastures or lots that have not held livestock for at least 2 weeks.[300,303,304]

Currently, no antimicrobial drugs in the United States are labeled for use against infectious foot rot in sheep, so use is extralabel. One-time treatment without foot trimming can produce similar results to foot bathing. Parenteral antimicrobials have produced recovery rates of 85% after one dose when sheep were kept on dry floors for 24 hours after treatment.[300] Although *D. nodosus* has been reported to be sensitive to many antimicrobials in vitro, this gives no indication of sensitivity when used clinically.[304] Medications used successfully have included procaine penicillin G (20,000 to 30,000 IU/kg IM twice daily),[303] long-acting oxytetracycline (20 mg/kg SC once, or repeated in 72 hours),[303,304] erythromycin (10 mg/kg once, or 3 to 5 mg/kg IM twice daily),[303,304] florfenicol (20 mg/kg IM, repeated in 48 hours),[303] and lincomycin (5 mg/kg SC once) in combination with spectinomycin (10 mg/kg SC once).[304] Maintaining dry footing for 24 hours,

yielding meat- and milk-withdrawal times, and the potential of reinfection are important considerations when using parenteral antimicrobials.[300]

Vaccination against *D. nodosus* is available, and its use in the treatment and control of foot rot has been reported.[300,301,303,304,308] A reduction in disease severity and quicker response to treatment may be evident when this is used as a treatment modality. Several strategies have been used for classifying *D. nodosus* strains, based on fimbrial types, and at least 10 serogroups with 19 serotypes have been identified.[300,302–304,306,307] Fimbrial gene variation undoubtedly plays an important role in vaccine efficacy.[304] The current commercial vaccine available contains 10 serotypes, and antigenic competition is likely to impede additional serotypes.[300,304] Identifying the most prominent strain or fimbrial type in a geographic region or flock may facilitate vaccine selection and development. Eight strains of *D. nodosus* have been reported to infect one foot.[304] Response to vaccination appears to be strain specific, with poor cross-protection between strains. Successful resolution of clinical signs by the use of an autogenous vaccine, without other treatments, has been reported.[308] The use of adjuvants in killed vaccines are required to produce an adequate antibody response, and the addition of adjuvants, particularly oil based, has led to a high incidence of injection site reactions.[300,303,304] The response to vaccination is likely short-lived, about 8 to 12 weeks,[300] and requires multiple doses. Vaccination of animals during the dry period, several weeks before the optimal transmission period, is likely beneficial in a control program.

Control and eradication can potentially be achieved in regions where the climate allows a break in the transmission period; however, the investment in labor and the cost of medical therapy may be high. A combination of topical treatment, parenteral antimicrobials, and vaccination is likely to be employed. Careful observation for early signs of infection and quarantine of any new animals are critical to controlling or preventing a flock outbreak. Using a weekly zinc sulfate footbath for 2 to 4 weeks, along with vaccination and culling of severe and unresponsive cases, has been suggested.[303] Based on evidence of resistance heritability, careful breeding programs should be explored.[301,304] Complete eradication from a farm can be achieved if the entire flock is removed, the facilities are left dormant for at least 2 weeks, and the flock is repopulated with noninfected animals.[300]

38.17.20 OTHER INFECTIOUS CONDITIONS OF THE FOOT

ROBIN M. DABAREINER

Infections involving the foot of horses and cattle are common and almost always caused by contamination from the environment gaining access to the soft tissue or bony structures of the foot within the hoof capsule. Typically the animal has an acute, progressive lameness such that the animal is almost non—weight bearing on the affected limb or will bear weight on the toe region of the foot but resist putting the heel on the ground. Other clinical signs include increased digital pulse pressure, heat and sensitivity to hoof tester pressure over the affected area. Regional nerve blocks can be used to localize the lameness to the foot but frequently are not necessary. Because the foot is encased in a shell of horny tissue, exudate from an infectious process often accumulates between the soft tissue and horn. The exudate then spreads or dissects along that plane until it reaches a soft tissue surface such as the coronary band, especially near the bulbs of the heels, where rupture and drainage can occur.

38.17.21 PROBLEMS ASSOCIATED WITH HORSESHOE NAILS (“NAIL PRICK”)

38.17.21.1 History and Clinical Signs

Nail prick (“quicking”) refers to penetration of the sensitive hoof structures, usually the sensitive laminae, by a driven horseshoe nail. The horse will usually react as the farrier drives or clinches the nail by jerking the foot from the farrier. In some cases, blood may appear on the nail or leak from the nail hole. It is important to realize that nail pricks occur for many reasons and are not always caused by a misdirected nail. Poorly made shoes, nails that are too large, poorly placed nail holes, and faulty nails can also result in a nail prick. Horses with poor hoof quality, thin hoof walls, or flaring hoof walls can be difficult to nail and thus are at greatest risk. Fractious horses and young horses not previously shod may lean on the farrier or repeatedly pull the foot from the farrier, making nail driving difficult. Damage from an improperly driven nail can vary from minimal to serious infection.

38.17.21.2 Diagnosis

Diagnosis of a misdirected nail warrants great diplomacy from the veterinarian because many owners become unjustifiably upset with the farrier. Some horses will repeatedly stomp the affected foot or paw the ground immediately after shoeing. Others may point the affected limb after shoeing. Lameness may not be apparent immediately after shoeing and may occur days later when the nail hole becomes infected and the trapped pus begins to exert pressure. The horse usually becomes acutely lame and worsens over time unless treated. Some infected nail holes will travel up the lamellae (white line) and create an abscess or soft spot at the hairline of the coronary band. The abscess will be directly aligned with the hoof wall tubules, leading to the infected nail hole, which is an important diagnostic aid. Hoof tester examination, paying particular attention to pressure over the driven nails, is an essential diagnostic tool to locate the offending nail. Using a hammer to strike the outside hoof wall may also elicit a painful response over the nail. Increased digital pulse and heat may be present.

38.17.21.3 Treatment

Pricks from nails can be potentially serious and require immediate treatment. If the nail prick is discovered by the farrier at the time of shoeing, the nail is removed. The nail should be examined for moisture or blood. The nail hole can be irrigated with DMSO, povidone-iodine (Betadine) solution, or hydrogen peroxide. The nail hole is packed with iodine-soaked cotton and the nail hole left open. Often the nail is redirected, and no further treatment is needed. If the horse's immunization status is not current, a tetanus vaccine is given.

If the offending nail cannot be localized or the nail hole is infected, the shoe is removed. Hoof testers are then used to localize the painful nail hole. Frequently the pressure from the hoof testers will cause black, malodorous liquid “pus” to exit from the hole. The basis of treatment is to establish drainage. The infected nail hole often requires enlargement with a loop hoof knife or curette. Ideally a cone-shaped hole is made, with the larger opening at the bottom of the hoof. The hole is irrigated or the entire foot soaked in an Epsom salt—Betadine footbath for 20 to 30 minutes twice daily until the infection is gone. It is important to protect the foot from the environment (e.g., mud, dirt) by keeping the foot bandaged between foot soaks. Additional medications are usually not necessary unless involvement is extensive. Antiinflammatory medications may be beneficial to decrease pain. Once the infection has cleared, the shoe is replaced. The affected nail hole can be packed with iodine-soaked cotton and the horse reshod with a plastic pad covering the sole. Alternately, a

hole can be drilled into the shoe over the affected nail hole and the shoe replaced, leaving access to the infected area for daily irrigation and povidone-iodine packing.

38.17.21.4 Prognosis

Prognosis is usually good provided that minimal damage occurs to vital structures of the foot. Establishing drainage for sepsis is important to avoid potential complications, such as third phalanx osteomyelitis or coffin joint sepsis.

38.17.22 SUBSOLAR ABSCESS

Subsolar abscess is one of the most common causes of lameness in the horse and cow, but it is relatively rare in sheep and goats. In one study in cattle, 88% of cases of lameness were caused by problems in the hoof.[311] Most often, lameness is caused by a hole or crack in the horny sole, which then becomes packed with dirt, and eventually contamination extends to and is trapped within the sensitive soft tissue beneath the sole. Animals that are housed in filthy or muddy conditions and that have inadequate hoof care or overgrown feet are more prone to this problem. Horses taken from a very dry to a very wet environment, and vice versa, also tend to have a higher incidence of sole abscesses, apparently because of the sudden change in the moisture content of the hoof and the resultant cracking of the sole. Cattle with “corkscrew claw” (a hereditary condition) or other growth deformity in the claw are more prone to sole abscess. Puncture wounds or any form of trauma that introduces contamination to the soft tissue of the sole also may result in abscessation.

1239

1240

38.17.22.1 History and Clinical Signs

Subsolar abscess is a common cause of acute lameness seen in all horses. There is no signalment or breed disposition. “Gravel” is a lay term describing the assumed etiology in which a piece of gravel migrates proximally from the white line to coronary band, leaving an infected tract. Subsolar abscesses may originate from a penetrating wound in the white line, a nail hole, or a deep subsolar bruise. Lameness is usually acute and severe (grade 3 to 4 of 5) and may worsen over time until drainage is established. The horse will often point and may not bear full weight on the affected limb. Distal limb swelling often accompanies a subsolar abscess that has not had drainage established. Systemic signs of infection (fever, lethargy) usually are not associated with subsolar abscesses unless deeper structures are involved. The infected tract may migrate and open at the coronary band. Before breaking open, a soft, painful area can be located by digital palpation of the coronary band.

38.17.22.2 Diagnosis

Digital pulses are usually increased, and the hoof capsule may radiate heat. A focal painful area can usually (but not always) be located with careful hoof tester examination. Careful paring of the sole and frog may be helpful in locating the abscess, but the clinician must be careful not to damage good, healthy tissue looking for the infection site. Foot poultices and hot-water footbaths with Epsom salts will help eventually to localize the affected area. Gray or black malodorous liquid will leak from the infected tract (Fig. 38-34). Radiographs are useful to rule out other causes, such as third phalanx and navicular bone fracture. In some cases a gas or fluid pocket can be identified on radiographs.

38.17.22.3 Treatment

Treatment is aimed at establishing adequate drainage. If an opening in the tract is present at the solar surface, it should be enlarged just enough for good irrigation and drainage. This may or may not require sedation or peripheral anesthesia of the foot. If pink tissue or blood is encountered, debridement is discontinued. Large holes should be avoided to prevent solar corium protrusion, which can be a painful sequela to overzealous hoof paring. If drainage occurs at the level of the coronary band and solar surface, through-and-through lavage is beneficial. Debridement at the coronary band level should be minimal to prevent iatrogenic coffin joint contamination. Once drainage is established, the foot is protected from the environment and from recontamination with a foot bandage. Continued foot soaks in warm-water povidone-iodine and Epsom salt footbaths should be continued until sepsis and inflammation are eliminated. The shoe is replaced when the affected are is dry and cornified. Large areas may require a plastic pad under the shoe for solar protection. Antibiotics and NSAIDs are rarely needed, except in severe cases or if penetration of deeper structures has occurred. The patient's tetanus immunization should be checked and a booster injection administered if needed.

Fig. 38-34 Horse's hoof with a recently opened subsolar abscess demonstrating gray exudate.

38.17.22.4 Prognosis

Prognosis for simple subsolar abscess is excellent but worsens if complications develop in which deeper structures of the foot become involved.

38.17.23 DEEP PENETRATING INJURIES TO THE SOLE

38.17.23.1 History and Clinical Signs

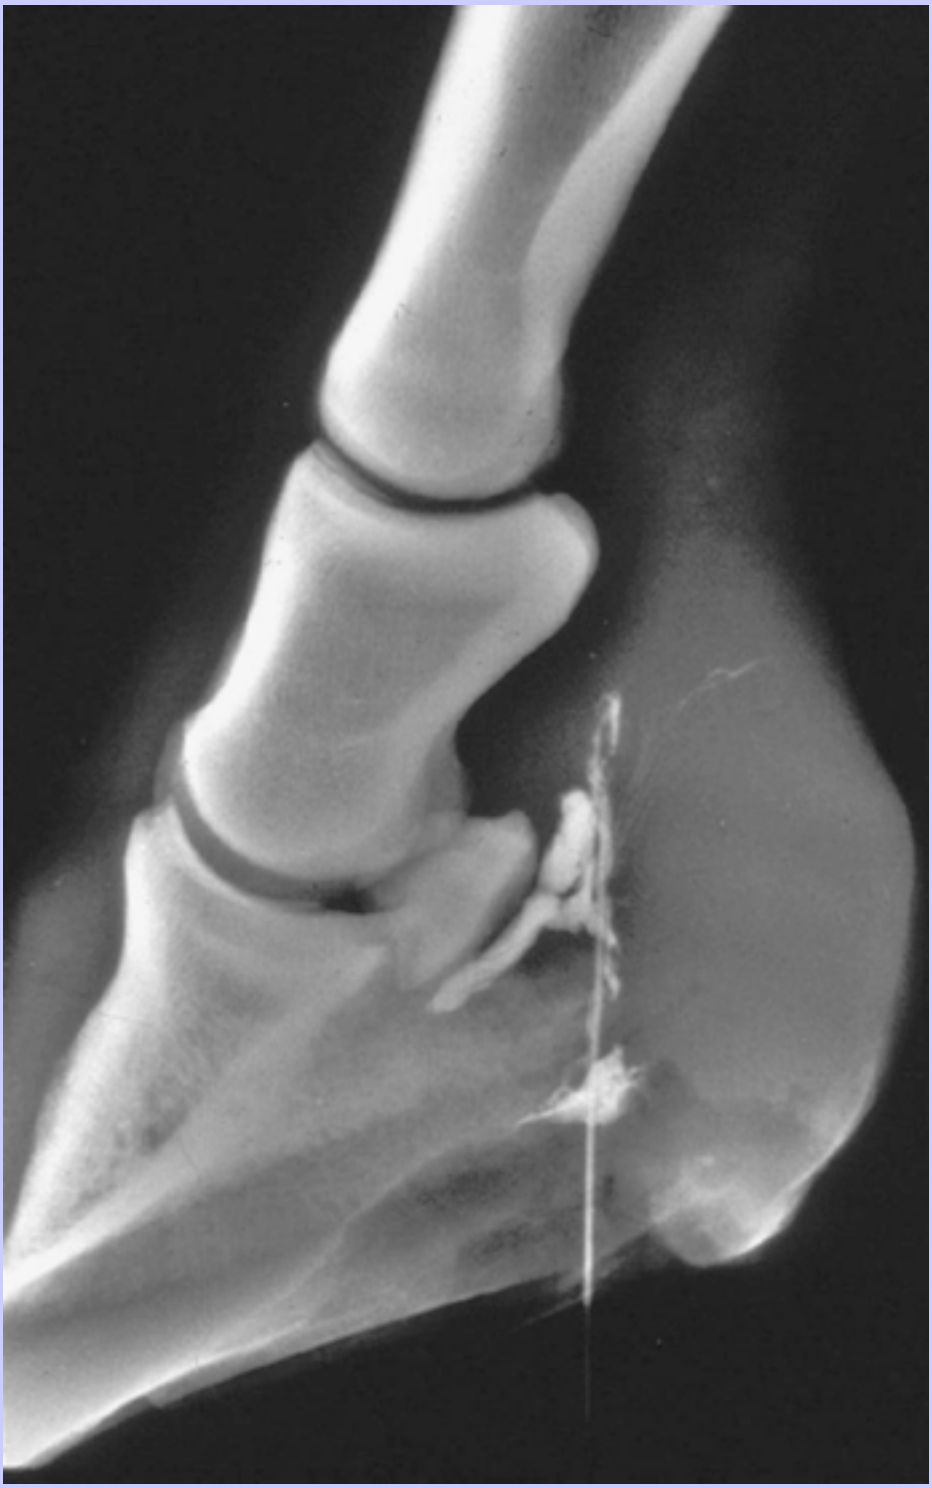
Most animals' environment is filled with sharp objects that can penetrate the sole, causing severe damage to structures deep within the hoof capsule. All puncture wounds should be considered potentially serious, but those involving the solar white line or caudal frog area require special attention because of potential navicular bursa, digital tendon sheath, deep digital flexor (DDF) tendon, or distal phalanx involvement.

The clinical signs of a penetrating wound to the sole vary with the anatomic structure involved and chronicity of the injury. The animal may show minimal lameness initially at the time of injury, but severe lameness once sepsis is established days later. Animals with penetrating wounds to the podotrochlear bursa or DDF tendon attachment to the third phalanx are in considerable pain and are reluctant to bear weight on the heel region.

38.17.23.2 Diagnosis

If owners find a foreign body in the bottom of the animal's foot, they usually should be instructed to leave the object in the foot unless there is danger of further penetration. A radiograph is taken immediately to determine depth of penetration. Digital pulses are increased, and the foot is usually warm to touch. Hoof testers are useful to determine the focal point of pain, but often the entire surface of the foot is reactive. Systemic sedation and peripheral anesthesia using an abaxial sesamoid nerve block may be needed to examine the penetrated foot thoroughly. Light paring of the sole and frog areas with a hoof knife may reveal a black spot indicating the penetration site. Often, however, the entry is not discovered because of the elastic nature of the hoof structures and collapsing of the penetration site. Regional intravenous anesthesia (Bier block) using a tourniquet is the method of choice for producing local anesthesia in cattle. Paring should be performed carefully so that the solar corium is not injured with the hoof knife. Because the corium represents the horn-producing epithelial covering of the foot, injuries to it heal the same way as skin injuries. If an entry wound is discovered, the foot is scrubbed and prepared for further diagnostic testing. A sterile, flexible probe can be gently inserted into the hole and a radiograph taken to determine the depth and direction of the hole. The clinician must be careful so that inadvertent force or horse movement does not cause the probe to penetrate previously unaffected structures. Alternately, a less invasive and preferred method is to catheterize 1240
or place a sterile teat cannula into the hole and inject sterile radiopaque material to determine which 1241
structures are involved (Fig. 38-35).

Fig. 38-35 Radiograph of a foot after injection of contrast dye to determine the path of the penetrating foreign body.



If sepsis of the podotrochlear bursa, distal interphalangeal joint, or digital tendon sheath is suspected, paracentesis and joint fluid cytology and culture and microbial sensitivity should be performed. Synovial fluid with an abnormal color, viscosity, elevated number of degenerative neutrophils, and high total protein concentration should suggest sepsis. If distal limb swelling is present, arthrocentesis should be delayed until the cellulitis subsides.

A series of radiographs should be taken to include a lateromedial, 60-degree dorsopalmar view of both the navicular bone and the third phalanx, and flexor (tangential) view of the navicular bone. Repeat examination 1 to 2 weeks after the original injury may be necessary because bony lysis takes time to develop and may not be apparent at the initial radiographic examination.

38.17.23.3 Treatment

Broad-spectrum systemic antibiotics, antiinflammatory medications, and tetanus prophylaxis are administered if penetration of deep hoof structures is suspected. Depending on the severity of the lameness, the animal may require an NSAID such as phenylbutazone (4 mg/kg twice daily in horses; 10 mg/kg once daily in cattle) to reduce pain and lameness in the initial stages. Antibiotic therapy should be continued for 2 weeks after resolution of clinical signs of infection in most cases. Preferably, antibiotics are initiated after a culture and microbial sample has been obtained. Establishment of drainage, copious lavage with sterile ionic fluid, and debridement of all necrotic tissue are indicated. Involvement of the podotrochlear bursa indicates use of navicular bursoscopy and aggressive medical therapy, consisting of daily lavaging of the bursa under general anesthesia and local treatment using antibiotics instilled within the bursa and regional limb perfusion. Surgical treatment such as the “street nail” procedure is reserved for animals not responding to aggressive medical therapy.

If the DDF tendon is involved (septic tendinitis), debridement and removal of frayed and infected tendon fibers may be performed in the standing, sedated horse using a tourniquet and peripheral anesthesia, or under general anesthesia, depending on horse temperament and owner financial constraints. After debridement, placing the horse in a 4- to 8-degree wedge shoe decreases weight-bearing forces on the DDF tendon and provides some pain relief. The wedge shoe angle is gradually decreased over several months as the DDF tendon begins to heal and strengthen. The bottom of the foot requires protection with a bandage or hospital plate until the surgical site granulates in and cornifies.

Deep penetrating wounds to the sole, especially the solar—white line junction, can result in infectious osteitis of the distal phalanx. The horse usually presents with a chronic, recurrent draining tract at the coronary band or solar surface and varying degrees of lameness. Infection of the distal phalanx often results from undetected soft tissue infection or dissecting subsolar abscesses. Septic pedal osteitis may also be a sequela to laminitis secondary to recurrent abscessation and ischemia at the toe region. As the bone infection progresses, blood supply to the area is compromised, and the area of avascular bone separates from the parent bone, forming a sequestrum. Localized third phalanx septic osteitis and sequestrum formation may not become radiographically evident for weeks after the initial penetration injury. Radiology often reveals a radiolucent area within the margins of the third phalanx, with or without sequestrum formation.

Debridement and curettage of all soft and necrotic bone can usually be performed in the standing, sedated animal if its temperament permits. The foot is desensitized with peripheral anesthesia, cleaned with a hoof knife and steel brush, then prepared for aseptic surgery using standard techniques. Hemostasis is achieved by wrapping a roll of Vetrap firmly around the fetlock joint to compress and occlude the palmar digital arteries.

Access to the infected bone is made by removing sequential layers of sole using either a motorized Dremel tool or a Galt trephine with a retractable pilot bit.[312] The infected bone is usually discolored and soft and should be curetted to healthy bone margins. The infected bone should be cultured and undergo microbial sensitivity testing. A postoperative radiograph should be taken to ensure complete debridement. After surgery the site is packed with sterile gauze sponges soaked in antiseptic or antimicrobial solutions, and then the foot is bandaged. Disposable diapers and duct tape are inexpensive materials for a waterproof foot bandage. The bandage is changed every 1 or 2 days for the initial few weeks. Application of a bar shoe and hospital plate provides solar protection and decreases the labor and cost of daily bandage changes (Fig. 38-36). The bolts and metal plate are removed so that the surgical site can be cleaned and treated, and then the hospital plate is bolted back in place.

After surgery the horse is confined to a small area until the hole granulates in and cornifies, usually 4 to 6 weeks. If granulation tissue becomes excessive at the surgical site, application of 2% tincture of iodine will hasten healing. If severe infection is present, the site can be packed lightly with antibiotic-impregnated beads for continued antibiotic release at the infected site. Regional limb perfusion with antibiotics is also beneficial in severe cases. 1241 1242

Fig. 38-36 Treatment plate for medicating an open wound in the bottom of a horse's foot.

In cattle, simple sole abscesses may heal quite satisfactorily without bandaging. In cows, use of a wooden block on the unaffected claw of the affected foot elevates the affected claw to a non—weight-bearing level and greatly reduces lameness. The block is attached with an epoxy such as Technovit and allowed to wear off over a period of weeks.

38.17.23.4 Prognosis

Prognosis depends on severity of injury, structures involved, and chronicity of the problem before initiating treatment. Horses with acute penetration wounds that receive immediate and aggressive treatment have a good chance of returning to athletic use. Penetration injuries that have an established infection involving the podotrochlear bursa, digital tendon sheath, or distal interphalangeal joint have a poor prognosis. In one study, only 12 of 38 horses with sepsis of the navicular bursa had a satisfactory outcome.[313] Chances of survival increased if treatment was started within a week of the penetration injury. Osteomyelitis of the navicular bone and DDF tendon rupture are common complications of a septic navicular bursa.

Prognosis for infectious osteitis of the distal phalanx is good if sepsis is not caused by laminitis. In one study, up to 24% of the distal phalanx was removed, and the horse returned to athletic soundness.[314]

38.17.24 THRUSH

38.17.24.1 Definition and Etiology

Thrush is a bacterial infection characterized by an accumulation of black, malodorous, necrotic material usually originating within the central or collateral sulci of the frogs of the hoof. This degenerative condition may spread to involve deeper structures of the foot, such as the digital cushion, hoof wall, and heel bulb region of the foot, causing inflammation and breakdown of these structures.[315] Many keratolytic organisms may be present, but *Fusobacterium necrophorum* is often isolated. Thrush is most often caused by poor environmental conditions; animals standing in soiled stalls, deep mud, swampy land, or wet pastures are at risk for developing thrush, especially if the feet are not cleaned daily. Another predisposing factor is poor hoof conformation. Saddlebreds, Tennessee Walkers, and other gaited horses have long feet with naturally deep frog sulci and are at risk of thrush.[316] Horses with sheared heels or acquired frog deformity are also predisposed. Horses shod with full pads may develop thrush secondary to moisture and dirt collection under the pad. Other, well-kept, clean horses can develop thrush for no apparent reason.

38.17.24.2 Clinical Signs and Diagnosis

Lameness may or may not be present, and the severity can vary. Diagnosis is based on the presence of black, malodorous discharge, most often within the frog sulci. The central frog sulcus is often malformed and very deep. A painful response may occur when the affected sulci are cleaned because the degenerative process may extend to sensitive structures of the foot. If structural damage has occurred, the heels may move independently of each other, causing pain on manipulation. Horses with mechanical instability of the heels may show caudal heel pain.

38.17.24.3 Treatment

The basis for treatment is removing the predisposing cause of the thrush. The horse should be moved to a clean, dry environment and have the feet cleaned daily. Any necrotic debris and undermined tissue are carefully debrided and cleaned using a hoof knife. Foot bandages may be necessary if the debridement is extensive. Systemic antibiotics may be necessary in severe cases that involve deep or more proximal tissues. Infection is usually managed by topical medication. Several caustic materials have been recommended, including a combination of phenol, tincture of iodine and 10% formalin, Kopertox solution, or methylene blue. Others have recommended soaking the foot in chlorine bleach (1 oz bleach per gallon water). If poor hoof conformation is the cause, proper farrier management should be pursued to correct existing problems. If heel instability is present, a bar shoe may be necessary to stabilize the caudal aspect of the foot. Exercise is important to strengthen the caudal aspect of the foot and will naturally clean the feet. The best treatment for thrush involves prevention by educating the client on proper hoof hygiene.

38.17.24.4 Prognosis

Prognosis is favorable if the cause of thrush can be identified and eliminated and if the condition is treated before extensive hoof damage has occurred.

38.17.25 WHITE LINE DISEASE (“SEEDY TOE”)

38.17.25.1 History and Clinical Signs

The white line, visible at the sole, is created by the junction of the insensitive laminae of the hoof wall and the horn of the sole. White line disease has historically described the separation of the hoof wall from its laminar attachments. A crack or opening occurs within the white line, allowing a bacterial or fungal infection to invade the stratum medium close to the laminae, causing cavities to develop between the laminae and outer hoof wall. In environmental conditions with too much moisture (continuous wet pastures) or in drought conditions producing excessively dry feet, animals are at risk of developing a crack or opening in the white line. Horses with poor-quality hoof walls that split or crack may develop white line disease. In addition, horses with chronic laminitis having a thickened or stretched white line in the toe region (“seedy toe”) are predisposed (Fig. 38-37). 1242 1243

Fig. 38-37 Stretched white line secondary to chronic laminitis.

The hoof wall separation is usually a chronic condition beginning weeks or months before presentation. Horses with white line disease often show little or no lameness and therefore are not perceived as an immediate concern by many owners. Hard ground may exacerbate any lameness seen.

38.17.25.2 Diagnosis

Visual examination of the white line, assisted by a probing instrument, will reveal a cavity with separation of outer hoof wall from the laminae. Radiographic evaluation will determine the full extent of hoof wall separation. Often the cavity is either dry or filled with necrotic debris, which may involve a bacterial or fungal infection. The cavity is usually not painful to probing.

38.17.25.3 Treatment

Treatment begins with removal of the separated outer hoof wall using a hoof nippers, hoof knife, and motorized tools. It is important to remove any unattached or loose hoof wall to reveal cracks or crevices that could harbor bacteria. The Dremel tool burr is useful to smooth any cracks in the insensitive laminae that are exposed after hoof wall removal. After thorough debridement, large defects usually exist in the hoof wall and require protection (Fig. 38-38). A heart-bar shoe redistributes weight-bearing forces to the frog and caudal region of the foot and away from damaged and weakened areas. The hoof wall defects prevent normal nailing procedures, and shoe clips can help secure the shoe to the hoof. After hoof wall removal, the exposed laminae may still have an “active” infectious component. With the heart-bar shoe in place, the owner is instructed to keep the horse in a clean, dry stall and topically treat the exposed laminae with iodine or methiolate daily for 10 days or until the exposed laminae are dry and “inactive.” At this point, the horse may be a candidate for prosthetic hoof wall repair using a product such as Equilox. The plastic acrylic is trimmed and shaped to the horse's natural hoof wall at the next shoeing. The owner should keep the hoof dry to avoid losing the acrylic patch. The horse may return to normal activity once the prosthetic patch is in place.

Fig. 38-38 Hoof with white line disease after the undermined hoof wall has been removed.

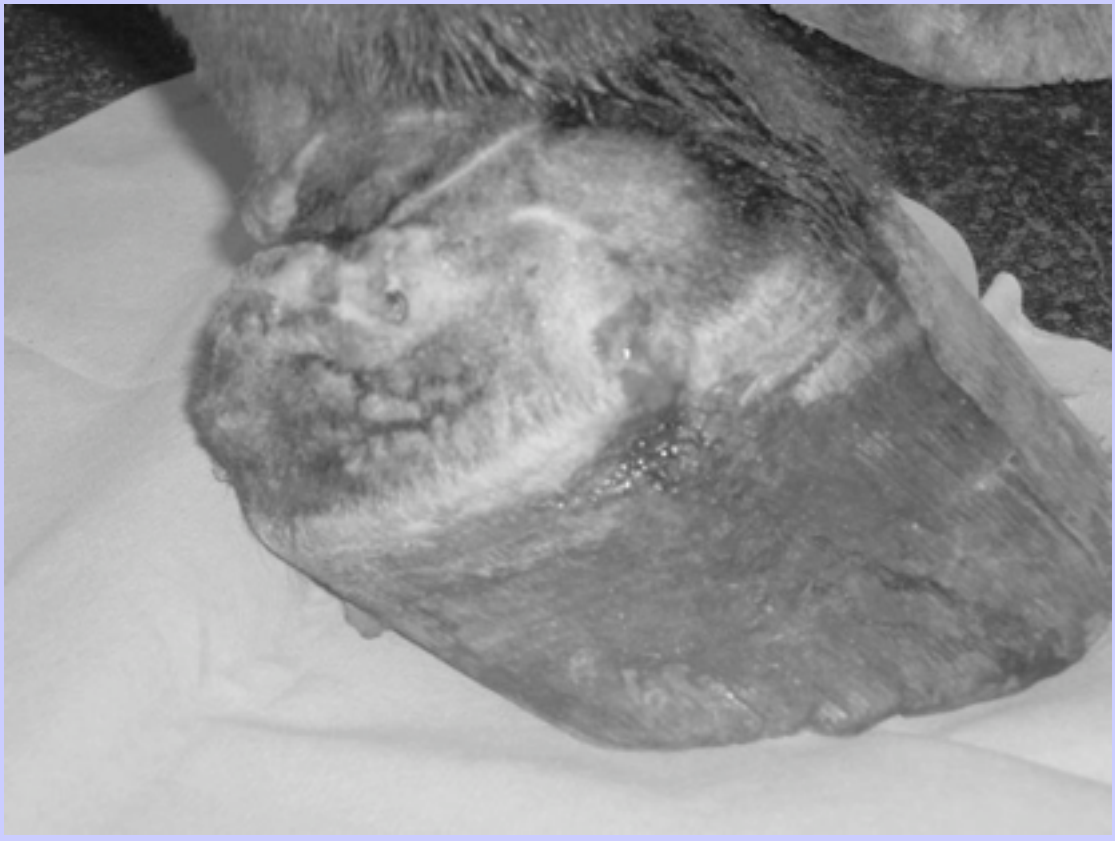
38.17.25.4 Prognosis

Prognosis depends on response to treatment and cause of the original white line problem. Horses with poor hoof quality or seedy toe will often have disease recurrence. If the horse responds to original treatment and environmental conditions improve, prognosis is good.

38.17.26 QUITTOR

Quittor is a term used to describe chronic infection of the medial or lateral collateral cartilage of the distal phalanx in the horse. This condition is characterized by local inflammation and necrosis of the affected cartilage, with subsequent formation of draining tracts proximal to the coronary band. The infection is usually caused by a wound, and the horse often presents with moderate to severe lameness and a history of chronic or recurrent drainage. Obtaining a dorsopalmar radiographic view after injecting contrast dye into the draining tract helps to demonstrate the infected collateral cartilage (Fig. 38-39).

Fig. 38-39 Horse's hoof with an infected collateral cartilage.



Although this condition occasionally responds to medical therapy, the treatment of choice is surgical debridement with the horse under general anesthesia, the foot in full extension, and a tourniquet around the pastern. An elliptical section that includes the draining tract should be incised above the coronary band and

discarded. All underlying infected soft tissue and necrotic cartilage should be excised. If the case has not become chronic and only a small amount of cartilage needs to be removed, the wound may be packed and partially sutured. The pack can be removed in 24 to 48 hours and the wound flushed twice a day until it has healed. If the condition is chronic with extensive cartilage necrosis or multiple draining tracts, the infectious process usually extends below the level of the coronary band. In this case it is best to trephine a hole in the hoof wall at the lowest point of the infection. This procedure provides better drainage, facilitates debridement of the necrotic cartilage, and allows for complete closure of the surgical incision above the coronary band. The wound should be packed through the trephine hole and treated as an open wound until it heals. In cases with extensive cartilage necrosis, care should be taken to avoid accidental opening of the coffin joint. If debridement is complete, the prognosis for the return to soundness is fair to good.[317]

38.17.27 FISTULOUS WITHERS

SARAH M. REUSS

38.17.27.1 Definition

Fistulous withers is a chronic inflammatory condition of the supraspinous bursa and associated tissues in horses and mules. The supraspinous bursa is located dorsal to the dorsal spinous processes of the second through fifth thoracic vertebrae (T2 to T5). The normal bursa may extend laterally to the scapular cartilage and may be asymmetric. Normal bursal volumes range from 30 to 90 mL.[318]

38.17.27.2 Clinical Signs

Affected horses may show nonspecific signs, including lethargy, fever, and generalized muscle stiffness. These may progress to the more specific signs of pain, heat, and swelling of the withers and cervical area. Over days to weeks, these swellings mature and rupture at one or more locations, releasing serous or purulent drainage. The classically described discharge is yellowish brown and mucoid or serous with white, yellow, or red flakes (“rice bodies”).[319] Fistulous tracts may extend to the dorsal spinous processes of the vertebrae, as well as to the scapula, ribs, and occasionally the thoracic cavity. Lesions and drainage may wax and wane.[318]

38.17.27.3 Etiology and Pathophysiology

There are two forms of fistulous withers: idiopathic and traumatic. The more common *idiopathic* form results from the spread of inflammation and infection of the supraspinous bursa to surrounding structures, including the nuchal ligament. Organisms reported to be the primary cause of fistulous withers include *Brucella abortus, Actinomyces bovis,* and *Onchocerca cervicalis. B. abortus* has a predilection for synovial structures and is often associated with septic supraspinous bursitis. In 1937, *B. abortus* was isolated from 80% of fistulous withers cases; 92% of affected horses had contact with cattle, and 65% were from farms with *Brucella*-positive cattle.[319] Currently, the disease has some geographic variability. In New York, where the prevalence of *B. abortus* infection in cattle is low, *B. abortus* is rarely isolated from equine cases of fistulous withers. In 1988 the prevalence of *B. abortus* in horses presented to the New York State College of Veterinary Medicine had apparently decreased, with only 2 of 14 horses (14%) having positive titers.[320] In Texas, however, where seropositive cattle are still prevalent, 9 of 28 horses (37.5%) with fistulous withers were seropositive for *B. abortus,* and these horses were more likely to be pastured with seropositive cattle.[321]

Researchers have also experimentally produced fistulous withers by injecting *B. abortus* and *A. bovis* into the supraspinous bursa.[322] *O. cervicalis* has also been proposed as an etiology for fistulous withers, especially in Australia. This parasite migrates through the nuchal ligament causing inflammation, which may extend to the supraspinous bursa. Fibrous and calcified tracts develop around dead and viable parasites, causing necrosis and degeneration of the nuchal ligament.[323]

The traumatic form of fistulous withers is preceded by an open wound or blunt trauma to the withers and then secondary infection. Infection may result from external contamination or from hematogenous spread to devitalized tissue. Secondary contamination of open wounds with *Streptococcus equi* subsp. *zooepidemicus*[320] or environmental microorganisms is reported.

38.17.27.4 Diagnosis

A careful history must be obtained, including duration and severity of clinical signs and response to previous treatment. Physical examination with careful palpation over the withers may reveal pain, swelling, or draining tracts. Complete blood count may show leukocytosis caused by neutrophilia, as well as hyperfibrinogenemia, indicating chronic inflammation.

If the swelling is encapsulated and not draining, needle aspiration should be performed to obtain a sample for culture and sensitivity. Once tracts are open and draining, culture is of questionable validity because of secondary bacterial contamination. Negative cultures can also be misleading because *B. abortus* is difficult to grown in culture and may be overgrown by other bacteria. Biopsy of inflamed tissue may also be obtained for culture and histology. Blood cultures may also be diagnostic in febrile animals.

All animals with fistulous withers should have serology for *Brucella* performed because of the public health implications. Plate agglutination is the test of choice and is more sensitive and specific than the card test. *Brucella* titers are considered to be negative when they are less than 1:50. Ideally, paired titers should be performed, with any rise in titers 2 weeks apart indicative of current infection.[324] Chronic infections may not show an increase, however, so a single high titer with compatible clinical signs should be considered diagnostic.

Radiographs should also be obtained in suspected cases of fistulous withers. They may show osteomyelitis and periostitis of the dorsal spinous processes of T1 to T9. There may also be swelling or granular opacity of the soft tissue in the withers region.[320] Horses with positive *B. abortus* titers are more likely to have radiographic evidence of osteomyelitis of the dorsal spinous processes than seronegative horses.[321] A positive-contrast fistulogram may help determine the extent of any draining tracts. Ultrasonography may also help delineate draining tracts.

38.17.27.5 Treatment

Medical treatment may be attempted but is often unsuccessful alone. Antimicrobial selection should be guided by culture and sensitivity results. In the absence of a culture, systemic broad-spectrum antimicrobials may be used. This can also be combined with lavage of the draining tracts. Systemic antiinflammatories are also indicated to control pain.

Brucella vaccination with the S19 strain has been reported in *Brucella*-confirmed cases as an effective extralabel treatment. The vaccination regimen varied from single-dose subcutaneous (SC) injection, to a

series of three SC injections 10 days apart, to intravenous (IV) injection. In 1937, Duff[319] reported that 95 of 134 horses that received two or three SC injections recovered after vaccination; 35 of these horses were also treated surgically. SC injection reportedly causes severe local and systemic reaction, including fever and abscessation.[324] The IV route may also be used, but it resulted in death in three of four horses; the other horse fully recovered in 4 weeks.[321] At this time, there are no approved vaccinations for use in horses, and the RB51 vaccine has not been used in equids. Also, the apparent decline in frequency of *Brucella* in fistulous withers would make vaccination of questionable value.

Medical management usually needs to be combined with aggressive surgical debridement for effective treatment. Conservative treatment alone may lead to recovery periods of 4 or more months. Reportedly, 80% of horses with traumatic fistulous withers treated conservatively will have recurrent lesions.[325] Drainage and debridement with the horse standing has been performed, but general anesthesia with aggressive debridement is the preferred treatment.[320] Ostectomy and curettage of the dorsal spinous processes may be necessary. Primary closure is difficult to achieve but will provide a more cosmetic result and quicker healing time. Wounds left open to heal by second intention may take 2 to 4 months to heal.[320]

38.17.27.6 Prevention and Control

Brucella abortus infection, if present, carries great public health implications. Horse owners and veterinary staff must be notified of the possible exposure and take appropriate precautions. Brucellosis in humans may cause acute fever with pneumonia, spondylitis, orchitis, or pyelonephritis. Chronic brucellosis causes a transient fever in people.[318]

Parasite control is an important aspect of prevention of fistulous withers. Horses should also be kept separate from *Brucella*-positive cattle. Proper saddle and harness fit will also decrease the incidence of traumatic fistulous withers.

38.17.28 FLEXURAL LIMB DEFORMITIES

A. BERKLEY CHESEN

38.17.28.1 Definition

Flexural limb deformities are defined as hyperflexion or hyperextention of a limb. Flexural deformities are described by the joint involved, typically the *distal interphalangeal* (DIP) joint, *metacarpophalangeal* (MCP) or *metatarsophalangeal* (MTP) joint, carpus, and rarely the tarsus. Although commonly referred to as "contracted tendons," the tendons themselves are not truly contracted, but rather short relative to the adjacent bone. Flexural limb deformities can be classified as either congenital or acquired. Contractural deformities are very common in horses and cattle. Small ruminants and camelids are much less frequently affected.

38.17.28.2 Pathogenesis

Congenital flexural deformities (deformed at birth) are likely caused by a multitude of factors. Although intrauterine positioning has been suggested, it is probably not a common cause of flexural limb deformities. Exposure of the mare during pregnancy to diseases and teratogenic agents is a more likely cause of congenital deformities. Evidence for a definitive inciting cause is lacking, but the following have been

implicated in contributing to flexural limb deformities: ingestion of locoweed *(Astragalus)* and hybrid Sudan grass, equine goiter, defective cross-linking of collagen, defects in elastin formation, neuromuscular disorders, and viruses.[326–329] It is common for foals with congenital flexural deformities to have other anatomic abnormalities, such as spinal deformities, which may result in dystocia.

Fig. 38-40 Contractural deformity of the distal interphalangeal joint (clubbed foot).

Acquired flexural deformities are seen typically from 4 weeks to 4 months of age, as well as in yearlings to 2-year-olds. These deformities have been implicated as part of the developmental orthopedic disease complex. Two general theories explain how acquired flexural deformities occur. The first theory is that the tendon unit is unable to elongate passively relative to the bone.[330] In the case of the DIP joint, the rigid accessory ligament of the *deep digital flexor* (DDF) tendon causes a palmar rotation of the foot (club-footed) (Fig. 38-40). Flexural deformities in the MCP joint are usually caused by the accessory ligament of the *superficial digital flexor* (SDF) tendon. The second theory is that increased tension within the tendon induces pain, leading to the deformity.[331] Acquired deformities are often noticed with an acute onset, which may add validity to the latter theory.

38.17.28.3 Diagnosis

38.17.28.3.1 CONGENITAL DEFORMITIES

Digital hyperextension deformities occur in neonates because of a lack of tension in the flexor muscles. Typically these deformities correct without intervention after a few weeks. In severe cases the palmar or plantar surfaces of the foal's pastern and fetlock area may become ulcerated as a result of contact with the ground, if not protected.

Contractural deformities may involve one or a combination of the following: SDF tendon, DDF tendon, and suspensory ligament. Congenital flexural deformities are most often seen affecting the carpus, tarsus, MCP joint, and MTP joint[332] (Fig. 38-41). Contracture of the DIP joint also occurs and presents with the foal walking on the toes. Depending on the severity of the deformity, if the MCP joint is affected, the foal may or may not be able to stand. Although not truly a contractural deformity, rupture of the *common digital extensor* (CDE) tendon results in a similar appearance. These foals have a characteristic swelling on the dorsolateral aspect of the carpus. Often these foals bow at the carpus because of the lack of support over the lateral aspect of the carpus.[326,333] More importantly, foals with ruptured CDE tendons should be checked for incomplete ossification of cuboidal bones because these conditions often occur together.[330]

Fig. 38-41 Contractural deformity of the metatarsophalangeal joint.

38.17.28.3.2

ACQUIRED DEFORMITIES

Contractural deformities are typically described by the joint affected. The most common acquired flexural deformity involves the DIP joint. The affected limb will have a steeper hoof wall angle with a shorter toe than the unaffected limb. The heel will elongate on the affected limb, and the MCP joint will concurrently begin to hyperextend. Two stages have been used to describe contractural deformities of the DIP joint: Stage I is defined as an angle of less than 90 degrees between the dorsal hoof wall and the sole; stage II is a dorsal hoof wall that exceeds the vertical angle.[334]

Early detection of contracture of the MCP joint is characterized by a straight fetlock angle, or upright conformation. More severe contracture of this joint is evident by buckling at the fetlock. By placing pressure in a dorsopalmar direction on the fetlock, the flexor tendons are stretched, allowing the practitioner to determine which structure is tightest, which is important for selecting an appropriate treatment.[330]

Carpal contractures tend to occur within the first 6 months of life. These foals tend to be fast-growing, heavier foals (Fig. 38-42).

Although not as common, contractural deformities of the *proximal interphalangeal* (PIP) joint occur and are usually bilateral.[330] The exact mechanism is unknown, but it is thought that as the musculotendinous unit of the DDF complex shortens, the SDF tendon becomes more lax.[335] This can lead to a dorsal subluxation of the joint. Often a clicking sound is appreciated when the foal walks. This contractural deformity is most often seen in weanlings with a high growth rate.[330]

Fig. 38-42 Bilateral, mild carpal contractural deformity.

Flexural deformities also occur after foals or horses are non—weight bearing for a time. These deformities can be permanent if the joint undergoes “contracture” or fibrodesis (fixed without osseous ankylosis).[330]

38.17.28.4 Treatment

38.17.28.4.1 CONGENITAL DEFORMITIES

Hyperextension deformities require exercise to hasten recovery. Excessive exercise is contraindicated because this leads to fatigue and possible injury. Treatments include swimming, corrective shoeing, and light bandaging when indicated. Swimming allows muscle tone to increase without bearing weight on the limbs. If the foal's toe lifts off the ground when weight bearing, glue-on shoes with a heel extension may be indicated. Glue-on shoes must not be left on a growing foal for an extended period because they may prevent the foot from expanding normally. Bandaging is only indicated when the palmar/plantar surface of the pastern or fetlock is in contact with the ground, to prevent ulcerations of the skin. Excessive bandaging and support will only cause more laxity and should be avoided.

Treatment for congenital contractural deformities should include pain management by judicious use of NSAIDs. The use of gastroprotectants is strongly suggested to help avoid the ulcerogenic effects of NSAIDs.

Oxytetracycline at a dose of 44 mg/kg diluted in physiologic saline given slowly IV has been used for many years in foals with contractural deformities.[336] Renal function of the foal should be considered before administration of oxytetracycline. Many mechanisms have been proposed to explain how oxytetracycline achieves a decrease in the angle of the MCP joint. One mechanism is the chelation of calcium resulting in muscle contraction.[336] Oxytetracycline has also been shown to be a neuromuscular blocking agent, although this mechanism does not explain why other muscle groups are unaffected.[336] An in vitro study showed that oxytetracycline also works through matrix metalloproteinase-1 mRNA expression to inhibit tractional organization of collagen fibrils by myofibroblasts; this interaction may cause relaxation of the musculotendinous unit.[337] Regardless of the mechanism of action, foals treated with oxytetracycline should also undergo forced exercise to make the improvement permanent. Without exercise, the angle of the MCP joint tends to return to its previous value within 96 hours.[338]

Toe extensions benefit the foal in two ways: (1) helping to protect the toe from being overworn and (2) lengthening the breakover of the foot, adding strain to the flexor tendons, potentially helping stretch them. Toe extensions may be made using acrylic hoof products or glue-on shoes with built-in extensions. Shoes and extensions should be removed within 2 weeks because they can prevent the hoof from growing and expanding naturally in a young foal. Typically, 2 weeks is sufficient time to achieve correction. For foals with contracture of the DIP joint, frequent rasping of the heels will help stretch the DDF tendon.

Splints and casts have been used to treat flexural deformities by giving support to the limb, thereby allowing the muscle-tendon unit to relax. When using splints, it is vital to use plenty of padding on the limb and to change the padding every time the splint is changed, to ensure pressure sores are not developing. Pressure sores can be very serious and even life threatening. Splints are made from a variety of materials but most often, polyvinyl chloride (PVC) pipe cut to an appropriate length and width; commercially made splints are also available. Splints are applied by placing the splint over the padding on the palmar or plantar surface of the limb. If the contractural deformity involves the DIP joint, the splint

should touch the ground. If the deformity is in the carpal region, the splint should end at the fetlock. Splints should be left in place for a period deemed adequate for the individual patient, ranging from several hours to 2 or 3 days.[330,332] One major advantage over casts is that splints may be removed every few hours if desired. Casts used for the lower limb are typically half-limb casts, incorporating the foot. The exception is the carpal region, where a tube cast is more appropriate, ending at the fetlock. Casts should never be left in place longer than 2 weeks at a time because of the rapid growth rate of foals. Cast sores are a serious complication and a legitimate disadvantage to using casts.

A combination of conservative treatments should be considered when treating foals with contractural deformities. If nonsurgical management does not correct the problem, surgical intervention may be necessary; however, foals with severe congenital contractural deformities have a poor prognosis. Surgery is more often attempted for foals with carpal contracture. Other congenital contractural deformities usually respond to nonsurgical treatments. Surgical correction for contractural deformities in the carpal region involves transection of the tendons of the flexor carpi ulnaris and ulnaris lateralis, as well as transection of the palmar carpal fascia.[330,332] The prognosis for mild to moderate congenital flexural deformities is good for an athletic future if the foal improves over the first 2 weeks and is able to stand and nurse.[332] Contractural deformities that can be manually straightened have a much better prognosis than those that cannot be straightened.

Foals with ruptured CDE tendons are best treated nonsurgically. Affected foals should be confined to stall rest with the application of a splint.[333] As with any splint, it should be well padded to protect the limb. The splint will provide support to the limb and help protect immature cuboidal bones, which often accompany this condition.[330]

38.17.28.5

ACQUIRED DEFORMITIES

Conservative management for acquired contractural deformities is similar to that for congenital deformities. Other conservative therapies include dietary restrictions, including early weaning. Surgical management is selected for animals unresponsive to nonsurgical treatments.

For contractural deformities of the DIP joint, desmotomy of the accessory ligament of the DDF tendon is indicated. This surgery has an excellent prognosis for full athletic potential for stage I horses. For more severe flexural deformities of this joint (stage II), a tenotomy of the DDF tendon may be necessary.[339] This procedure is not performed to promote an athletic career. It is acceptable for pasture soundness, breeding animals, and for some, light riding.

Acquired flexural deformities of the MCP joint are treated nonsurgically with a combination of NSAIDs, corrective shoeing (raising the heel with or without using a vertical bar shoe with rubber dorsal tubing) and splints. Physical therapy has been used to help stretch the tendons by having the horse hop on one leg by holding the other up in a flexed position, moving in a lateral direction toward the down limb.[330] If surgical correction is needed, it is important first to determine which structure is creating the tension. Most often the SDF tendon is involved, although the DDF tendon and even the suspensory ligament may be involved. For treatment of contracture of the SDF tendon, desmotomy of its accessory ligament is performed. If the DDF tendon is the most taut, desmotomy of its accessory ligament is completed. Both accessory ligaments may be cut when indicated. In severe cases the suspensory branches may be transected, but this procedure is done for salvage because it usually leads to subluxation of the PIP joint.[330]

Carpal contractures are treated with splints and controlled exercise. Early weaning should be considered in these foals. If surgery is necessary, a tenotomy of the flexor carpi ulnaris and ulnaris lateralis in addition to splints may yield good results.

Contracture of the PIP joint is not as common but can be a serious threat to the future athletic potential of the horse. Over time the soft tissues around the joint will fibrose, and the PIP joint may undergo degenerative joint disease. At this stage, a pastern arthrodesis may be necessary to achieve a pain-free and potentially sound limb. Desmotomy of the accessory ligament of the DDF tendon may benefit affected horses early in the disease process.[330,335]

38.17.28.6 TENDINITIS

ELIZABETH J. DAVIDSON

38.17.28.6.1 Definition and Etiology

Tendon injuries can have a profound influence on the future athletic careers of horses. The superficial digital flexor (SDF) tendon is the most frequently injured tendinous structure in the performance horse.[340] It occurs more frequently in the thoroughbred and standardbred racehorse, although it is typically seen in all types of performance horses. Deep digital flexor (DDF) tendon injuries in the metacarpal/metatarsal region occur infrequently[340–342] and are identified in older horses (9 to 10 years)[341–344] and in horses that jump.[343] Western performance horses more often have hindlimb deep flexor tendinitis (or tendonitis), probably because of their sudden turns and quick stopping in roping, cutting, or reining competition. Recently, DDF tendinitis has been identified as the major contributor of lameness in horses with foot pain.[343,345] Desmitis of the accessory ligament of the DDF tendon[346] and the accessory ligament of the SDF tendon[347] are unusual injuries in performance horses.

Tendons passively transfer muscle activity to the bone. In the equine distal limb, the palmar tendons act to support the fetlock during normal weight bearing and must withstand high—tensile stress forces during locomotion. To combat these forces, tendons contain a high proportion of type I collagen, and the tendon fibers are aligned longitudinally. When loaded, these fibers deform elastically by stretching. Normally, substantial elongation, up to a 20% increase in length,[348] occurs before failure. In thoroughbred horses, normal SDF tendons have stains reaching up to 16% when galloping.[349] This suggests that tendons in racehorses are close to their physiologic limit and may explain the high incidence of injury. Also, age-related and exercise-related tendon matrix deterioration may contribute to tendon weakness.[350] In addition, landing after a jump increases the SDF load,[351] which may explain the incidence of tendon injury in horses used for Grand Prix jumpers and eventing.

Tendon injury may occur as a single event or a cumulative fatigue failure and involves stretching of the fibers beyond physiologic limits. Response to tendon injury is similar to other tissue healing and includes inflammation, repair, and remodeling. During the acute inflammatory phase, hemorrhage and edema occur, and the degree of the response is determined by severity of the injury. Angiogenesis quickly follows, and recruited fibroblasts produce new type III collagen. A fibrinous scar of weak, haphazardly arranged collagen is formed. At this stage the tendon is prone to reinjury. Finally, the scar tissue remodels over several months, converting type III collagen to type I collagen. Controlled loading of the tendon

promotes this conversation and aligns the collagen fibrils in the direction of force (longitudinally). In severely injured tendons the entire process can take 12 or more months, and tendon reinjury is common.

38.17.28.6.2

Clinical Signs

Clinical signs of acute SDF tendon injury include swelling and heat in the tendon and peritendinous tissues. Thickening or enlargement of the tendon is noted when it is viewed from the lateral aspect, and the classic convex or bowed profile in the metacarpal region is apparent. A painful response to direct digital palpation can be appreciated and is best performed by holding the leg and palpating the tendon between thumb and forefinger. Unless the injury is severe, most horses with tendinitis are not lame.

Horses with DDF tendinitis are moderately lame,[341,342] become more lame after distal limb flexion, and have distention of the distal digital tendon sheath.[341] Injuries are usually unilateral.[341,342] Horses with DDF tendon injuries within the hoof capsule have unilateral or bilateral lameness without any palatable abnormalities.[343,345] Horses with desmitis of the accessory ligament of the DDF tendon have obvious swelling and acutely are moderately to severely lame.[346] Thickening and effusion in the carpal canal may be noted in horses with desmitis of the accessory ligament of the SDF tendon.

38.17.28.6.3

Diagnosis

Diagnosis of SDF tendon injury in the metacarpal region is obvious based on abnormal clinical signs. Diagnostic analgesia may assist the clinician in localization of the tendon injury if clinical signs are subtle or absent. This is particularly true for DDF tendon injury within the hoof capsule. Pain from DDF tendon injury in the distal metacarpal region can improve after intrasynovial analgesia of the distal digital tendon sheath.[341] Antebrachial or proximal metacarpal analgesia alleviates pain from accessory ligament of the SDF tendon.[347]

Ultrasonography is the technique of choice to diagnose tendinitis, and considerable advances in instrumentation and clinical aptitude have occurred in the past decade. The entire palmar/plantar area of the metacarpus/metatarsus should be examined in transverse and longitudinal planes. The variables typically measured include cross-sectional area, echogenicity, and fiber alignment. The severity of the injury is determined by the length of the lesion, cross-sectional area of the tendon, cross-sectional area of the lesion, lesion echogenicity, and fiber alignment of the lesion.[340,352,353] The severity rating score has been correlated with successful outcome. The most common type of SDF tendon injury is a central core lesion that appears as an anechoic lesion.[340,352]

Tendon injuries of the DDF within the hoof capsule have been identified using transcuneal ultrasonography.[344] Clinician expertise and meticulous foot preparation are required. With the advent of MRI, DDF tendon injuries within the foot have been described. Injury types include core lesions, sagittal tears, and fibrillation along the dorsal border, and most lesions occur at or near the navicular bone.[343,345,354]

38.17.28.6.4

Treatment

Proper treatment of tendinitis includes assessment of the injury using ultrasonography, control of the acute inflammatory episode, controlled return to function, and adjunct medical/surgical therapy. In acute injury,

a combination of systemic NSAIDs (e.g., phenylbutazone, flunixin meglumine) and topical therapy (e.g., cold-water hydrotherapy, poultice, distal limb bandage) is recommended. DMSO and antiphlogistically impregnated gauze bandages may also be beneficial. Rest is essential during the acute phases.

A variety of intratendinous and peritendinous injections have been advocated. Intralesional corticosteroids dramatically decrease the swelling and pain but cannot be recommended because of delayed tendon healing and the risk of continued injury and catastrophic injury in horses that remain in training. β-Aminoproprionitrile fumarate (BAPTEN) temporary blocks the cross-linking between collagen fibers and improves tendon healing, resulting in superior fiber alignment;[355] horses with moderately to severely injured tendons were more likely to return to racing after intralesional treatment.[356,357] This treatment has fallen out of favor because of complications associated with the procedure. For DDF tendon injuries, intrathecal injections of sodium hyaluronate into the distal digital tendon sheath are beneficial.[358] Intralesional sodium hyaluronate for SDF tendonitis has been advocated,[359] although other reports failed to document any significant benefit.[357,360] Intramuscular polysulfated glycosaminoglycan (GAG) has a positive effect on tendon healing in a collagenase-induced model.[361] However, no difference in return to racing or recurrence of SDF tendinitis has been demonstrated with intralesional or intramuscular polysulfated GAG.[357] Newer therapies include intralesional injections of urinary bladder matrix powder and stem cells derived from fat or bone marrow. Long-term effects have yet to be determined.

Surgical treatments include tendon splitting,[362] desmotomy of the superior check ligament,[363–366] and desmotomy of the palmar/plantar annular ligament.[367] Tendon splitting is believed to enhance revascularization and has a tendency toward improved tendon repair.[362] It is currently used for in horses with core lesions to decompress areas of hemorrhage. Superior check desmotomy may improve the likelihood that horses return to racing[363] and is clearly beneficial in standardbred racehorses.[363,364] In thoroughbred racehorses, postoperative success was initially promising;[365] however, no difference between horses treated conservatively and horses treated with desmotomy has been reported.[366] In addition, desmotomy may predispose horses to desmitis of the suspensory ligament.[364,366] Annular desmotomy has been successful performed in horses with signs of annular ligament constriction[367,368] and is usually combined with superior check desmotomy.[368] Immediate decompression and improved gliding function are presumed benefits.

Other therapies for SDF tendinitis include therapeutic ultrasound, low-power laser treatment, and extracorporeal shock wave therapy. Counterirritation (internal or external blisters) and pin firing in combination with controlled exercise or turnout in a large pasture are time-honored treatments, but their effects on tendon healing have been questionable.

Controlled exercise in combination with the previous treatments guides the repair process in hopes of producing a functional tendon or tendon substitute. If exercise is excessive, fibrous tissue is produced rather than remodeled. If no stress is applied, the tendon is more adapted to pasture exercise than performance. Therefore, the exercise regimen must be adapted to the individual patient's needs. Depending on the severity of the tendon injury, stall rest with hand walking and gradual introduction of trot is indicated. Horses should be monitored every 2 months using ultrasonography until they have returned to their previous athletic function or have failed to do so. The exercise program is dictated by the amount and type of healing. As the tendon heals, its echogenicity increases and short, linear echoes are detected. With continued healing, there are longer linear echoes and improved fiber alignment. Decrease in the cross-

sectional area is a good indication that the tendon is healing and remodeling. Ideally, complete repair will occur, and the tendon will no longer have a discretely visible area of injury because it has filled in with tissue that is isoechoic with normal tendon, and fiber alignment is parallel to normal.[352] 1248 1249

38.17.28.6.5 Prognosis

Prognosis for horses with SDF tendinitis depends on the severity of the lesion and the type of athletic work performed. Racehorses usually have a poorer prognosis, and 58% return to racing with severe injuries, 66% for moderate injuries, and 64% for mild tendinitis.[369] Most horses treated with superior check desmotomy returned to racing; however, recurrence[363–365] and suspensory desmitis[364,366] may develop. Show horses have a higher likelihood of return to function,[357] and many can continue to compete, although at a lower level. Horses with DDF tendon injuries have a poor prognosis.[341,343,345] Prognosis for horses with desmitis of the accessory ligament of the DDF tendon is good.[346] Prognosis for horses with uncomplicated desmitis of the accessory ligament of the SDF is fair, although horses with concurrent injuries are likely to have recurrent lameness.[347]

38.17.28.7 SUSPENSORY LIGAMENT DESMITIS

ELIZABETH J. DAVIDSON

38.17.28.7.1 Definition and Etiology

Suspensory ligament desmitis is a common injury of performance horses and affects all breeds of horses. Injuries to the ligament occur in both the forelimbs and the hindlimbs, and bilateral desmitis may be seen. The suspensory ligament, also named the third interosseous muscle, can be divided into three regions of interest: the proximal (origin) portion, the body, and the branches. The proximal portion originates from the distal row of carpal or tarsal bones, the proximal palmar/plantar aspect of the third metacarpus/metatarsus, and the palmar carpal or tarsal ligament. The body of the suspensory ligament descends between the second and fourth metacarpal/metatarsal bones and then divides into the medial and lateral branches in the middle metacarpal/metatarsal region. The branches insert on the abaxial surface of their respective sesamoid bones. The main function of the suspensory ligament is to support the hyperextension of the metacarpophalangeal or metatarsophalangeal joint during weight bearing.[370] Injury to the ligament occurs when it is overwhelmed with stress and its structural integrity is compromised. The damage induces a repair process characterized by inflammation (desmitis) and fibroplasia. It is surmised that this process is similar to tendinitis.[370]

Catastrophic traumatic disruption of the suspensory apparatus occurs almost exclusively in the forelimbs of thoroughbred racehorses. It is the most common cause of racetrack breakdown injuries.[371] Fatigue and high speed are components of this career-ending injury.

Degenerative suspensory desmitis is a progressive degeneration primarily affecting the suspensory branches. It is most often reported in Peruvian Pasos,[372] although has been identified in other breeds. The pathogenesis remains unclear, although the disease appears to run in families.[373] This disorder has no gender or age predilection and can occur in the absence of athletic activity. Affected horses have

continuous enlargement of the suspensory ligament because of ineffective collagen fiber repair and generalized interstitial and periligamentous fibrosis.[372]

38.17.28.7.2

Clinical Signs

Clinical signs of acute suspensory ligament desmitis include local heat, swelling, and sensitivity on palpation. In horses with proximal suspensory desmitis, swelling is in a palmar or plantar direction and frequently mild and transient because of the bony borders of the ligament. Most horses are lame, and the degree and duration of lameness depend on location and severity of the lesion. The lameness is usually worse when the horse is trotted in a circle with the affected limb on the outside of the circle. Lameness and local signs may resolve after a short period of rest and antiinflammatory treatment.

Acute, severe traumatic disruption of the suspensory apparatus results in obvious swelling, grade 4 to 5 lameness, and a hyperextended fetlock. Affected horses require first-aid treatment by application of a splint that aligns the metacarpus with the phalanges in a straight column to prevent fetlock bending.

Clinical signs of chronic suspensory desmitis include thickening of the body and branches of the ligament. Lameness is variable and may be bilateral. Chronic desmitis is typically associated with sesamoiditis, periostitis, or fractures of the small metacarpal/metatarsal bones and sesamoid bones. Straight hock conformation and hyperextension of the fetlock joints appear to be predisposing factors in proximal hindlimb suspensory desmitis, and affected horses are chronically lame despite rest.[374] Degenerative suspensory desmitis is characterized by recurrent chronic lameness, marked fetlock swelling, dropped fetlocks, excessive lying down, and reluctance to move. The majority of horses will be affected in all four limbs.[372]

38.17.28.7.3

Diagnosis

If suspensory desmitis is suspected and clinical signs are not obvious, diagnostic analgesia techniques assist in the localization of the lameness to the palmar/plantar metacarpal/metatarsal region. If proximal suspensory desmitis is suspected, perineural analgesia of the lateral palmar nerve[375] or deep branch of the lateral plantar nerve just distal to the tarsus[376] will alleviate the lameness in the forelimb or hindlimb, respectively. Desmitis of the suspensory body and branches can be localized using low palmar/plantar analgesia.

Diagnosis of suspensory desmitis is confirmed by ultrasound examination. The severity of the lesion is assessed by obtaining cross-sectional and longitudinal views of the ligament and cross-sectional area measurements. Ultrasonographic changes include cross-sectional area enlargement, focal or diffuse areas of hypogenicity, core lesions, loss of normal fiber pattern, and periligamentous thickening. Mild injuries to the suspensory ligament may be difficult to identify because of the wide variation in its normal ultrasonographic appearance. This is especially true in the proximal region, where the suspensory ligament origin is more heterogenous than for other tendons and ligaments because of a variable amount of muscle tissue. Comparison of the affected and nonaffected limbs in the same horse is recommended because of large variation among breeds and individuals.[370,377]

Radiographic examination is useful for identification of the bony abnormalities usually noted with suspensory desmitis. Bony abnormalities such as subchondral sclerosis, avulsion fracture, and enthesophyte formation have been identified in horses with proximal suspensory desmitis.[378,379] “Blind

splints" associated with axial exostosis of the second and fourth metacarpal/metatarsal bones or fractures may also contribute to suspensory desmitis. Proximal sesamoiditis and apical sesamoid fractures may be noted in horses with desmitis of the suspensory branches. In acute traumatic disruption of the suspensory apparatus, comminuted fractures of both proximal sesamoid bones are common.

Nuclear scintigraphic findings are normal in the majority of horses with suspensory desmitis.[380] Increased radiopharmaceutical uptake associated with the proximal palmar/plantar metacarpus/metatarsus can be identified in horses with avulsion fractures and other stress-related bone injuries seen in complex suspensory desmitis.[378,379] Recently, MRI evaluation has been used to diagnose proximal suspensory desmitis and fibrous adhesions between the suspensory ligament and the small splint bones.[381]

38.17.28.7.4

Treatment

Treatment of acute suspensory desmitis is aimed at reducing inflammation by the administration of systemic NSAIDs, local cold hydrotherapy, limb bandage, and controlled exercise. Initial clinical signs often dissipate quickly, even though there may be significant fiber disruption of the ligament; therefore it is strongly recommended to assess the initial injury using ultrasonography. In uncomplicated desmitis, a controlled exercise program may be initiated as soon as the acute inflammation has resolved. The duration of rehabilitation will depend on the extent and severity of the desmitis. Fractures of the small metacarpal/metatarsal bones or proximal sesamoid bones should be removed before rehabilitation. Horses are confined to a stall and hand-walked. Ligamentous healing should be monitored every 60 days using ultrasound. Ideally, there should be a progressive reduction in cross-sectional area, improved echogenicity, and fiber alignment. A gradual increase in exercise can be prescribed depending on healing.

Damaged suspensory ligaments have been injected with various corticosteroids, iodine compounds, sodium hyaluronate, and polysulfated glycosaminoglycans in an effort to reduce inflammation and promote a more rapid return to function. Pin firing, blistering, and cryotherapy with liquid nitrogen have also been used. Although these therapies assist with the initial inflammation, they do not restore normal fiber architecture and can put the ligament at increased risk because of overuse of the horse based solely on reduction of clinical signs.

Recurrent or chronic proximal suspensory desmitis has been treated successfully with extracorporeal shock wave therapy.[382] Other treatments, such as plantar metatarsal neurectomy,[383] intralesional injection of autologous stem cells,[384] desmotomy,[385] and fasciotomy,[383–385] have also been beneficial.

For horses with acute traumatic suspensory desmitis, it is crucial to place in the affected limb in a protective splint that aligns the metacarpus with the phalanges in a straight column to prevent fetlock bending. Successful nonsurgical management using splints, casts, and special shoes to support the fetlock has been reported.[386] Surgical management involves fetlock arthrodesis using dorsal plating.

For horses with degenerative suspensory desmitis, treatment is palliative and consists of stall confinement for 6 to 12 months and extended heel or large egg-bar shoes. Humane euthanasia is recommended with continued breakdown despite treatment.

38.17.28.7.5

Prognosis

The prognosis for horses with suspensory desmitis depends on the location and severity of the injury. Uncomplicated cases with minimal disruption of the ligament can recover and resume preinjury athletic function; 90% of horses with acute proximal suspensory desmitis in the forelimb will return to full athletic function.[387] Complicated, chronic, or recurrent desmitis has been associated with a worse prognosis; only 13% of horses with hindlimb proximal suspensory desmitis return to full work.[374] Most horses with traumatic disruption of the suspensory ligament can be salvaged for breeding, although meticulous nursing care in horses treated conservatively and uncomplicated surgical repair are imperative. Prognosis for horses with degenerative suspensory desmitis is extremely poor.

38.17.29

FRACTURES

TAMARA M. SWOR

The ability to treat fractures in large animals depends largely on rapid and correct diagnosis, appropriate first-aid treatment and stabilization of the injured limb, and safe transportation to a referral surgical center. Emergency treatment administered by a veterinarian in the field is crucial to provide the most treatment options and to enhance the prognosis. Accurate knowledge of available treatment options and the prognosis for various fracture types is critical during discussions with clients. The surgeon receiving a patient with a fracture should be contacted early and involved in the decisions regarding limb stabilization, transportation, and owner financial commitments. Treatment options are discussed in this section; specific surgical principles related to fracture repair can be found in surgical textbooks.

38.17.29.1

Definition and Etiology

A fracture is defined as a break or rupture of a bone. In large animals, fractures are usually classified as complete or incomplete, articular or nonarticular, displaced or nondisplaced, open or closed, simple or comminuted, and transverse, oblique, or spiral. Classification by location is also common and includes terms such as physeal, metaphyseal, and diaphyseal.

Fractures in large animals are typically associated with an acute traumatic event, followed by a sudden, severe lameness. Horses may have a history of falling or running into a solid object, receiving a kick from another horse, being hit by a car, or flipping over backward (typically young animals). In another common scenario, the owner hears a loud pop or cracking sound while the horse is being longed or is participating in an athletic activity.

Stress fractures may also occur and often are a result of cyclic loading over time with corresponding fatigue, leading to bone microfracture. Intensive training schedules create a high number of loading cycles with insufficient time to remodel and repair local areas of stressed bone (e.g., racehorse training). Specific locations of stress fractures include the distal end of the scapular spine, caudoproximal humeral head, craniodistomedial aspect of the humerus, medial humeral diaphysis, caudal aspect of the radius, dorsal middiaphyseal and distodorsolateral third metacarpal, caudal border of the ilial wing and adjacent to the pubic symphysis, proximolateral tibia, and caudal diaphysis of the tibia.[388]

Other, less common causes of large animal fractures include nutritional deficiencies, neoplasia, and infectious causes leading to pathologic fractures. Fractures related to difficult parturition events are seen in neonatal foals and calves.

38.17.29.2 Clinical Signs and Differential Diagnosis

An animal with a long-bone fracture will typically present with an acute, non—weight-bearing lameness of the affected limb. Moderate to severe soft tissue swelling and inability to control the limb often accompany other clinical signs of distress, agitation, and pain. Because of the horse's "fight or flight" reaction to traumatic situations, the patient will often continue attempts to place weight on the fractured limb. Fractures in locations with limited soft tissue coverage are often open (e.g., third metacarpal). Severe hemorrhage or laceration of large vessels is uncommon but may occur.

Complete, catastrophic fractures are often easily identified based on limb instability and soft tissue trauma or swelling. Proximal limb fractures may be difficult to palpate but have adjacent severe soft tissue inflammation and edema, crepitus, and difficulties in limb function. Nondisplaced or incomplete fractures may be associated with a wound or may be painful to manual palpation. Focal pain on palpation, a corresponding lameness, and a history of trauma or being kicked by another animal warrant radiographic evaluation in search of an incomplete fracture. An unrecognized incomplete fracture may progress to a complete fracture with time and exercise. Physeal fractures should be considered in young animals.

1250

1251

Stress fractures often present with a history of an acute, severe lameness followed by a rapid decrease in the degree of lameness. There may also be reports of intermittent lameness that improves with stall rest. Palpation of the limb often reveals a focal area of pain, heat, and swelling. The horse may resist manipulation of the limb.

Differential diagnoses should include hoof and sole abscesses, joint subluxation, joint luxation, nerve damage, soft tissue injury, and septic synovial structures.

38.17.29.3 Clinical Evaluation

A complete physical examination should be performed on initial evaluation. Animals that are not immediately identified as having a fractured limb may be in need of systemic support. Fluid therapy, pain control, antiinflammatory medications, and antimicrobials should be used as necessary.

Definitive diagnosis is made by taking multiple radiographic views; nuclear scintigraphy, ultrasonography, CT, and MRI may also be used. Information from imaging studies will provide fracture configuration details essential for determining prognosis. The bone involved, degree of comminution, articular involvement, physeal involvement, and condition of the bone fragments all affect potential repair attempts and long-term prognosis. Incomplete fractures may not be readily identified at the time of injury, and radiographs should be repeated in 10 to 14 days if a fracture is suspected.

Table 38-5 Emergency Splinting Techniques for Fractures in Large Domestic Animals

Location	Species/Age	Splint
Distal phalanx	Horses, foals Cattle, calves	No splint needed
Middle phalanx	Horses, foals	Bandage with dorsal (forelimb) or plantar (hindlimb) splint to proximal third metacarpal/tarsal and cast material, Kimzey splint*
Proximal phalanx	Horses, foals	Bandage with dorsal (forelimb) or plantar (hindlimb) splint to proximal third metacarpal/tarsal and cast material, Kimzey splint*
	Cattle, calves	No splint needed
Distal sesamoid (navicular)	Horses, foals	No splint needed
Proximal sesamoids	Horses, foals	
		Bandage with dorsal (forelimb) or plantar (hindlimb) splint and cast material, Kimzey splint*
Metacarpal/tarsal 3	Horses, foals	Bandage with dorsal (forelimb) or plantar (hindlimb) splint and cast material, Kimzey splint* if fracture distal
Metacarpal/tarsal 3 & 4	Cattle, calves	Bandage with dorsal (forelimb) or plantar (hindlimb) splint and cast, cast
Metacarpal/tarsal 2 & 4	Horses, foals	No splint needed
Olecranon/ulna	Horses, foals	Robert Jones—type bandage with caudal splint to lock carpus in extension
Radius	Horses, foals Cattle, calves	Robert Jones—type bandage with lateral splint to withers, second caudal splint if needed
Humerus	Horses, foals Cattle, calves	No splint needed
Scapula	Horses, foals Cattle, calves	No splint needed
Tibia	Horses, foals	Robert Jones—type bandage with lateral splint to tuber coxae
Femur	Horses, foals Cattle, calves	No splint needed
Pelvis	Horses, foals Cattle, calves	No splint needed

* Leg-Saver splint, Kimzey Inc, 164 Kentucky Ave, Woodland, CA 95695 (530-662-9331, fax 530-662-9178); http://www.kimzeymetalproducts.com.

Stress fractures also are diagnosed using radiographic evaluation and may be identified as an incomplete cortical fracture, endosteal callus, or periosteal callus.[389] As with incomplete fractures, it may be difficult to identify a stress fracture by conventional radiography in the acute stages. Radiographs should be repeated in 10 to 14 days if a fracture is suspected. Other imaging modalities, especially nuclear scintigraphy or CT, may be useful in stress fracture identification.

38.17.29.4

Emergency Treatment

The goals of emergency treatment include preventing further soft tissue damage, stabilizing the injured limb to decrease the patient's anxiety, minimizing further damage to the fractured bone ends, keeping the fracture closed, and preventing further injury and stretching to the surrounding vessels and nerves.[390] A large animal with a fractured limb should be immediately restrained and calmed. Sedatives and tranquilizers should be used with caution, however, because the desired result may be difficult to achieve if the animal is agitated or in shock. The goal of sedation should be to allow manipulation of the limb and placement of external coaptation. Common sedatives should be used with caution to avoid creating additional ataxia; butorphanol should not be used if the horse has sustained a front limb fracture because it will make the horse lean onto the forehand. If a soft tissue wound is present, the clinician should assume that the fracture is open. The wound should be cleaned, topical antimicrobials used, a bandage placed to prevent further contamination, and the animal started on systemic antimicrobials. Antiinflammatory medications should be used as necessary.

Appropriate external coaptation and stabilization of the fracture for transport can greatly influence the options available for fracture repair and the prognosis for success. Table 38-5 outlines specific emergency splints for different fractures in bones.[390,391] Splinting techniques are designed to be placed on the standing horse and attempt to neutralize forces acting on the fractured limb. Splints should be made of a strong, lightweight material such as polyvinyl chloride (PVC) pipe or wooden boards. Bandages over fractures should be placed tightly over the injured area to decrease soft tissue swelling and minimize slippage. A layer of cotton padding should be followed by a layer of gauze or a self-adhering bandage. Multiple layers can be placed if needed (e.g., Robert Jones—type bandage). The splint should not end at the fracture location. In general, splinting techniques can be divided into categories based on fracture location.

1251

1252

38.17.29.5

DISTAL LIMB FRACTURES (PHALANGES, DISTAL METACARPUS/METATARSUS)

A light cotton bandage should be placed on the affected limb from the carpus to the ground. A splint is then positioned on the dorsal aspect of a forelimb or the plantar aspect of a hindlimb. The toe is pointed toward the ground to align the dorsal cortices and to minimize stretching of the palmar/plantar vascular and nerve structures. A second splint should be placed on the medial or lateral side of the limb if any instability is present in those directions. The splint should be secured with inelastic tape. For additional stability, several rolls of fiberglass casting tape should be placed around the entire bandage and splint structure, incorporating the hoof into the cast.

38.17.29.6

MIDLIMB FRACTURES (MIDMETACARPUS TO DISTAL RADIUS, MIDMETATARSUS TO PROXIMAL METATARSUS)

A Robert Jones—type bandage should be placed on the limb from the ground to the elbow in a forelimb or the ground to the calcaneal tuber in a hindlimb. The bandage should be less extensive in the hindlimb to

facilitate splint placement. In the forelimb, splints should be placed on the lateral and caudal aspects of the limb from the ground to the elbow. In the hindlimb, splints should be placed on the lateral and caudal aspects of the limb from the ground to the calcaneal tuber. The splints are secured using inelastic tape, followed by several rolls of fiberglass casting tape around the entire structure.

38.17.29.7 UPPER LIMB FRACTURES (MIDDLE AND PROXIMAL RADIUS, TARSUS, TIBIA)

A Robert Jones—type bandage should be placed on the limb from the ground and extending as proximal as possible. In the forelimb, a splint should be placed on the lateral aspect of the limb from the ground to the withers. A second splint may be placed on the caudal or cranial side, from the ground to the proximal forearm, if needed for increased stability. Horses with olecranon fractures that disable the triceps muscle benefit from reestablishment of carpal extension by placement of a caudal splint. In the hindlimb, a splint should be placed on the lateral aspect from the ground to the tuber coxae. Splints placed high in this fashion will assist in minimizing abduction of the limb.

38.17.29.8 HIGH LIMB FRACTURES (PROXIMAL TO ELBOW JOINT, FEMUR)

Fractures in these locations are covered by extensive muscle, and attempts at splinting are usually unsuccessful and not helpful to the animal. If triceps muscle function is disabled, a splint on the caudal aspect of the carpus, locking it into extension, is beneficial.

38.17.29.9 TRANSPORT

Transportation of horses with long-bone fractures can be difficult. It is best to confine the patient in the trailer so that they may lean on dividers for support. The horse should be tied loosely in the trailer to prevent turning around, but allowing the animal to use its head for balance. When possible, horses with forelimb fractures should be transported with the head facing the rear of the trailer, and those with hindlimb fractures should be transported with the head facing the front of the trailer. These positions allow the horse to control its weight most easily with the uninjured limbs during deceleration of the trailer.

38.17.30 Pathophysiology of Bone Healing

Healing of a fracture terminates in the return of the injured bone to its original form.[392] The process of fracture healing involves several biologic steps that overlap and interact with each other. Typically, three phases are recognized: inflammatory, reparative, and remodeling.[392,393] The *inflammatory phase* occurs in the initial 2 to 3 weeks after bone fracture, and chemical mediators cause chemotaxis, migration of leukocytes, and vasodilation to the injured area. These mediators protect the injury from infection and stimulate angiogenic factors. Cytokines from platelets aid in angiogenesis and mesenchymal cell growth.[392] Granulocytes and macrophages destroy invading bacteria and stimulate cell repair through the release of growth and angiogenic factors. If the inflammatory phase is impaired, fracture healing may be compromised.[392]

The *reparative phase* overlaps with the inflammatory phase and may last up to 12 months. This phase attempts to reestablish bone union. Interfragmentary stabilization by periosteal and endosteal callus formation begins if the fractured ends are not immobilized.[393] Bony union develops as a result of endochondral and intramembranous ossification.[392,393] In the reparative phase, interfragmentary motion may greatly influence fracture healing.

The *remodeling phase* takes place both during and after the reparative phase. Osteonal remodeling allows for replacement of the necrotic regions of bone. When the bone is loaded, the negatively charged concave surface will attract osteoblasts to add new bone, and the positively charged convex surface will attract osteoclasts to remove bone.[392,393] The result is the ability of a fractured bone to straighten itself by creating new bone formation on the concave surface and removing bone from the convex surface.

Repair of a fractured bone with the use of rigid internal fixation will inhibit the naturally occurring callus formation and encourage bone to heal through haversian remodeling. *Haversian remodeling* requires that a fracture be rigidly fixed, have adequate reduction, and have an adequate blood supply.[392,393] Haversian remodeling then functions to revascularize necrotic bone at the fragmented ends of the fracture and bridge interfragmentary gaps. This form of remodeling begins 2 to 3 months after injury.

Fractured bones are often described as healing by primary (direct) or secondary (indirect) intention.[389,392,393] Primary bone healing only occurs with complete anatomic reduction and rigid stability. In large animal fracture repair, this is difficult to achieve because of the size of the animal and micromotion at the repair site.[389] Secondary bone healing utilizes endosteal and periosteal callus formation, and new bone formed at the fracture site develops after initial formation of fibrous tissue or fibrocartilage.[392,393]

The rate of bone healing may be decreased if blood supply is inadequate, infection is present, soft tissue damage is extensive, or stability of the bone fragments is inadequate.

38.17.31 Treatment and Prognosis

Treatment options for fractures in large animals include conservative therapy with stall rest and external coaptation (casts, splints) and surgical stabilization with open reduction and internal fixation. It is important to recognize incomplete and stress fractures in order to manage them appropriately with conservative therapy, preventing progression to a catastrophic fracture. The majority of fractures require some form of stabilization for the best chance of a successful outcome. Most horses require surgical stabilization for successful fracture repair. Ruminants are more amenable to successful fracture repair with nonsurgical options.[389] 1252 1253

Conservative therapy with stall rest and external coaptation may be successful in some foals and calves with complete, nondisplaced fractures. Young animals have a greater and faster ability to heal bone in a reasonable amount of time, and their body weight is much less than that of a mature animal. In foals and calves, the fracture configurations tend to be simpler, and the surgical implants available for repair are of a suitable strength compared to the animal's size. Complications in young animals include closure of a physes with fractures in these areas, infection, and angular limb deformities from overuse of the contralateral limb.

In adult animals, it is more common to identify severely comminuted fractures due to the large force needed for bone breakage. Proximal limb fractures in an adult horse are often unable to be successfully treated because severe comminution of the bone occurs, implants are not strong enough to support the bone until it is healed, these horses are less likely to protect the limb, and laminitis formation in the contralateral limb is a common complication. Stall rest with external coaptation alone is rarely associated with a good outcome, and most horses require some form of internal fixation for success. Horses are often required to be athletes, and fracture repair resulting in survival, but not soundness, may be unacceptable. In general, ruminants have a better prognosis for survival than horses because of their less excitable temperament, and complete soundness is often unnecessary for a successful outcome. External fixation may be more successful in ruminants than external

coaptation because it provides increased stability and costs less than internal fixation.[389] Open fractures in horses greatly decreases the prognosis for survival and may delay the ability to perform internal fixation. In ruminants, open fractures are less common but also carry a poorer prognosis.

Table 38-6 Treatment and Prognosis for Large Animal Fractures

Fracture Location	Fracture Type	Treatment	Prognosis
Distal phalanx	Articular	Medical/surgical	Guarded
	Nonarticular	Medical	Good
Middle phalanx	Comminuted	Surgical	Guarded
Proximal phalanx	Comminuted	Surgical	Guarded
	Noncomminuted	Medical/surgical	Good
Distal sesamoid	Fragmented	Medical/surgical	Poor to guarded
Proximal sesamoids	Articular	Medical/surgical	Poor to guarded
	Nonarticular	Medical/surgical	Fair to good
Third metacarpal/tarsal			
Lateral condyle	Nondisplaced	Surgical	Good
	Displaced	Surgical	Guarded
Medial condyle	Articular	Surgical	Guarded
Diaphyseal	Comminuted	Surgical	Guarded
Third and fourth metacarpal/tarsal	Diaphyseal	Medical/surgical	Good to excellent
Second and fourth metacarpal/tarsal	Distal	Medical/surgical	Good to excellent
	Proximal	Surgical	Guarded to good
Olecranon/ulna	Articular	Surgical	Good
	Nonarticular	Medical/surgical	Good
Radius	Complete	Surgical	Poor
	Complete*	Surgical	Guarded to good
	Incomplete	Medical	Good
Humerus	Complete	Medical	Poor
	Complete*	Surgical	Guarded to good
Scapula	Complete	Surgical	Poor to fair
Tibia	Complete	Surgical	Poor
	Complete*	Surgical	Guarded to good
Femur	Complete	Medical	Poor
	Complete*	Surgical	Guarded to good
Pelvis	Articular	Medical	Guarded
	Nonarticular	Medical	Guarded to good

* Foals, calves, and small ruminants.

Implants used for surgical open reduction and internal fixation methods vary based on the specific bone involved, the animal's age, the strength of the bone fragments used in the repair, and the surgeon's preference. Common implants used in large animals include intramedullary (IM) interlocking nails, dynamic compression plates (DCPs), locking compression plates, limited-contact DCPs, screws, wires, pins, and dynamic condylar screw plates. Table 38-6 lists specific treatment options and prognoses.[391]

38.17.32 HUMERUS

The humeral fracture is often in a spiral or long oblique configuration. In ruminant and equine species, both conservative and surgical treatments have been used. In foals, surgical repair may include the use of IM interlocking nails, DCPs, or IM nails. Prognosis for a closed fracture in a foal is fair to good and depends on configuration, age, and weight.[394,395] Humeral fractures in adult horses are not reparable at this time. Conservative treatment may be successful in adult horses with nondisplaced fractures and has been used in small ruminants and foals with acceptable outcomes. Ruminants have a better prognosis in general than equine species.[389]

38.17.33 RADIUS

Survival rates for ruminants with radial fractures repaired by external or internal fixation have been reported as 86%.[396] Radial fractures in foals repaired with internal fixation have a good prognosis; however, in adult horses the success rate is poor.[397] Animals with incomplete fractures that do not progress have a good prognosis for a full recovery.

38.17.34 OLECRANON

There are several different fracture configurations, and the olecranon fracture may be articular or nonarticular. These fractures are common in both young and older horses. Surgical and conservative treatments have been used with success, although internal fixation is the preferred treatment method.[398,399] Typically, the fracture is repaired with a DCP applied as a tension band. The prognosis with surgical repair is good, with 62%, 75%, and 87% of horses returning to athletic use, depending on the fracture type.[398–400] Conservative treatment has been reported to result in a 73% return to soundness.[401]

38.17.35 FEMUR

Diaphyseal fractures are more common in calves, whereas proximal physeal fractures are more common in foals.[389] Femoral fractures in calves may occur during parturition events. In young calves, these fractures have been repaired by internal fixation and femoral head and neck osteotomies with success. In foals, fracture repair with internal fixation gives the best chance of survival, and the use of IM interlocking nails has shown positive results.[402] Femoral fractures in adult horses are not reparable at this time.

38.17.36 TIBIA

Ruminants sustaining tibial fractures have been repaired using splints, external fixators, transfixation pin casts, and DCPs. Fractures repaired with external fixation in adult cattle had a 64% success rate, versus conservative therapy success at 44%.[403] Internal fixation is the repair method of choice in horses. Foals have a fair to good prognosis for survival. Adult horses have a poor prognosis for survival because tibial fractures are often open, have limited blood supply, and are often severely comminuted.

38.17.37 METACARPUS/METATARSUS

In cattle, these fractures are common and have a good prognosis when treated with internal fixation, casts, or transfixation pin casts.[389] Calves may incur distal physeal fractures after forced extraction during a dystocia, and these may be casted with good success. In horses, cannon bone fractures are frequently open because of a lack of soft tissue coverage. Treatment options include internal fixation with DCPs and screws or transfixation pin casts. One study reported a 67% success rate with surgical repair.[404]

38.17.38 PHALANGES

In ruminants, fractures of the proximal or middle phalanx are treated with reasonable success by applying a block to the uninjured claw or by cast application. In horses, proximal and middle phalangeal fractures have been treated by internal fixation with screws and DCPs. Prognosis for survival is good, but return to athletic function depends on the degree of osteoarthritis that develops after fixation. One review of proximal phalangeal fractures in racehorses reported that 61% to 75% were able to race.[405] Prognosis for comminuted middle phalangeal fractures repaired with proximal interphalangeal joint arthrodesis is 50% for forelimbs and 80% for hindlimbs.[389] Severely comminuted fractures may also be treated with transfixation pin casts or the Nunamaker external skeletal fixator. Fractures of the distal phalanx in horses may be successfully treated with surgical fixation, hoof casts, or modification in shoeing, depending on fracture configuration.[406]

38.17.39 SUMMARY

Animals identified with incomplete fractures should be treated conservatively with stall rest and should be tied to prevent them from lying down if the fracture is at risk of becoming complete (e.g., radius). Animals with stress fractures should be treated conservatively with stall rest and a careful rehabilitation program, with ongoing radiographic evaluation.

Many fractures in large animals are able to be repaired and allow survival of the animal. Prognosis in general is better if the animal is young, it weighs 500 pounds (225 kg) or less, the fracture is closed, appropriate emergency stabilization is implemented, and prompt reduction and stabilization are performed.

38.17.40 SPONTANEOUS FRACTURES IN RUMINANTS

JOHN MAAS

38.17.40.1 ## Definition and Etiology

Spontaneous fracture of bone is a syndrome that occurs when underlying bone disease weakens bone(s) to the point where otherwise normally applied stresses result in bone failure. The terms *spontaneous fracture* and *pathologic fracture* are synonymous for clinical usage. Fractured bones typically include (1) long bones of the limbs, (2) vertebrae, (3) ribs, and occasionally (4) the mandible or pelvic bones.

38.17.40.2 ## Clinical Signs and Differential Diagnosis

Clinical signs of postural deformity, swelling, and lameness are observed, with bone fracture resulting from minimal or no apparent stress. Thorough physical examination often reveals additional fractures that are in the process of healing, particularly of the ribs and long bones. A fracture that occurs in normal bone in response to applied stress is the main differential diagnosis.

38.17.40.3 ## Pathophysiology, Epidemiology, and Clinical Pathology

The specific causes of spontaneous fractures in ruminants are varied and include pathologic processes that affect the tensile strength of bone. Although spontaneous fractures are not common, certain disease processes predispose animals to this condition, including (1) tumors affecting individual bones, (2) osteomyelitis, (3) rickets (osteodystrophy) in young ruminants, (4) osteomalacia in adult ruminants, and (5) osteoporosis associated with copper deficiency.

The effect of localized infection or tumor growth is to weaken bone tissue by dissolution of the mineral matrix. More common tumors causing bone weakness and fracture include lymphosarcoma and primary bone tumors in ruminants. Osteomyelitis, as a primary condition or as an extension from septic arthritis, can severely affect the strength of bone over time. Osteomyelitis causing pathologic fractures can be associated with wounds or can occur in diseases such as actinomycosis.

Rickets in young, growing animals occasionally can result in spontaneous fractures of long bones and vertebrae. Osteomalacia in adult ruminants is caused by the same factors that result in rickets in young, growing livestock. As in young ruminants, the cause of osteomalacia is most often a deficiency of phosphorus or vitamin D. Calcium deficiency (primary or secondary), however, can be involved in the pathogenesis. Individual uremic animals may develop osteomalacia and spontaneous fractures from a lack of active vitamin D (1,25-dihydroxycholecalciferol). The pathogenesis of osteomalacia in the adult differs from that of rickets, in that mature and well-mineralized bone is removed and replaced by inadequately mineralized organic matrix. Therefore, radiographic and histologic examination of osteomalacic bone occasionally reveals signs of osteoporosis. Osteomalacia of the metaphysis and epiphysis is less prominent than with rickets. Spontaneous fractures associated with osteomalacia are usually accompanied by pica, skeletal deformities, and hypophosphatemia.

1254
1255

Copper deficiency can be caused by a lack of adequate dietary copper (primary) or a relative excess of sulfates and molybdenum (secondary), which bind copper and make it unavailable for metabolism, resulting in osteoporosis[407] (see Chapter 37). The biochemical mechanism of bony lesions in copper deficiency is unknown; however, lysyl oxidase, a copper-containing metalloenzyme, may be involved. Copper deficiency can be a significant cause of lameness even without spontaneous fractures.[408,409] Radiographic and histologic findings in affected bones of lame, copper-deficient ruminants are similar to those seen with

rickets.[410] Copper-deficient ruminants can also exhibit signs of anemia, achromotrichia, alopecia, diarrhea, poor growth, decreased feed efficiency, osteoporosis, and sudden death. Diagnosis of copper deficiency can be made when serum or plasma copper concentration is less than 0.5 μg/mL (ppm) or when hepatic copper concentration is less than 35 μg/g on a dry-weight basis. Differentiating primary from secondary copper deficiency requires the analysis of diet and water. In my experience with spontaneous fractures associated with copper deficiency, two additional findings are frequently seen: (1) concurrent selenium deficiency and (2) hypophosphorosis with adequate dietary calcium. Syndromes seen in the field may be more complicated than we currently understand.

There are a number of possible causes of spontaneous fractures in ruminants. Factors that might affect a group of animals include dietary deficiencies of phosphorus, calcium, copper, and trace minerals (Se, Mn, Zn); mineral (Ca, P, Mg) imbalances; indoor housing (vitamin D deficiency); protein deficiency (osteoporosis); rapid growth; lactation; and advanced pregnancy. The differentiation of spontaneous fractures from other causes of bone fractures is made by history, physical examination, and identification of one or more associated conditions mentioned previously.

38.17.40.4 Treatment and Prevention

Treatment of spontaneous fracture is similar to that of common orthopedic problems caused by trauma. In addition, the underlying condition(s) must be corrected. Although the prognosis must be considered guarded or poor, I have examined recovered and ambulatory cattle with multiple healing rib fractures and two healing long-bone fractures. With spontaneous fractures associated with osteomalacia, rickets, and osteoporosis caused by copper deficiency, the animals' ability to heal is remarkable. Prevention of spontaneous fractures depends on identifying and correcting all underlying problems.

38.17.41 BUCKED SHINS AND STRESS FRACTURES OF THE METACARPUS IN THE HORSE

SUSAN M. STOVER

38.17.41.1 Definition and Etiology

Bucked shins and stress fractures are the acute and chronic manifestations of disease of the dorsal cortex of the third metacarpal bone. Bucked shins is a painful condition most often involving the middiaphyseal dorsal cortex of 2-year-old and occasionally 3-year-old horses in their first year of race training.

Stress or fatigue fractures are incomplete fractures located in the mid-diaphyseal dorsal cortex and less often in the distal diaphyseal dorsal or dorsolateral cortex. These fractures are seen most frequently in 3-year-old horses but can also affect 2-year-old horses later in the racing season and, with decreasing numbers, older horses.

Bucked shins and stress fractures are occupational diseases of horses in race training. These conditions are more prevalent in young horses training at fast speeds on dirt surfaces than in older horses or horses training on grass surfaces.

38.17.41.2 Clinical Signs and Differential Diagnosis

A general pattern of clinical signs was observed in one study of 2-year-old thoroughbred horses in race training.[411] Bucked shins usually occurred bilaterally. Both metacarpi usually were affected simultaneously, although occasionally one was affected several days before signs were observed in the contralateral metacarpus. In most horses the first clinical indication of bucked shins was a painful response to palpation of the metacarpus. Subtle pain often was found before the detection of an unwillingness of the horse to work at fast speed. Lameness was not necessarily manifested by affected horses.

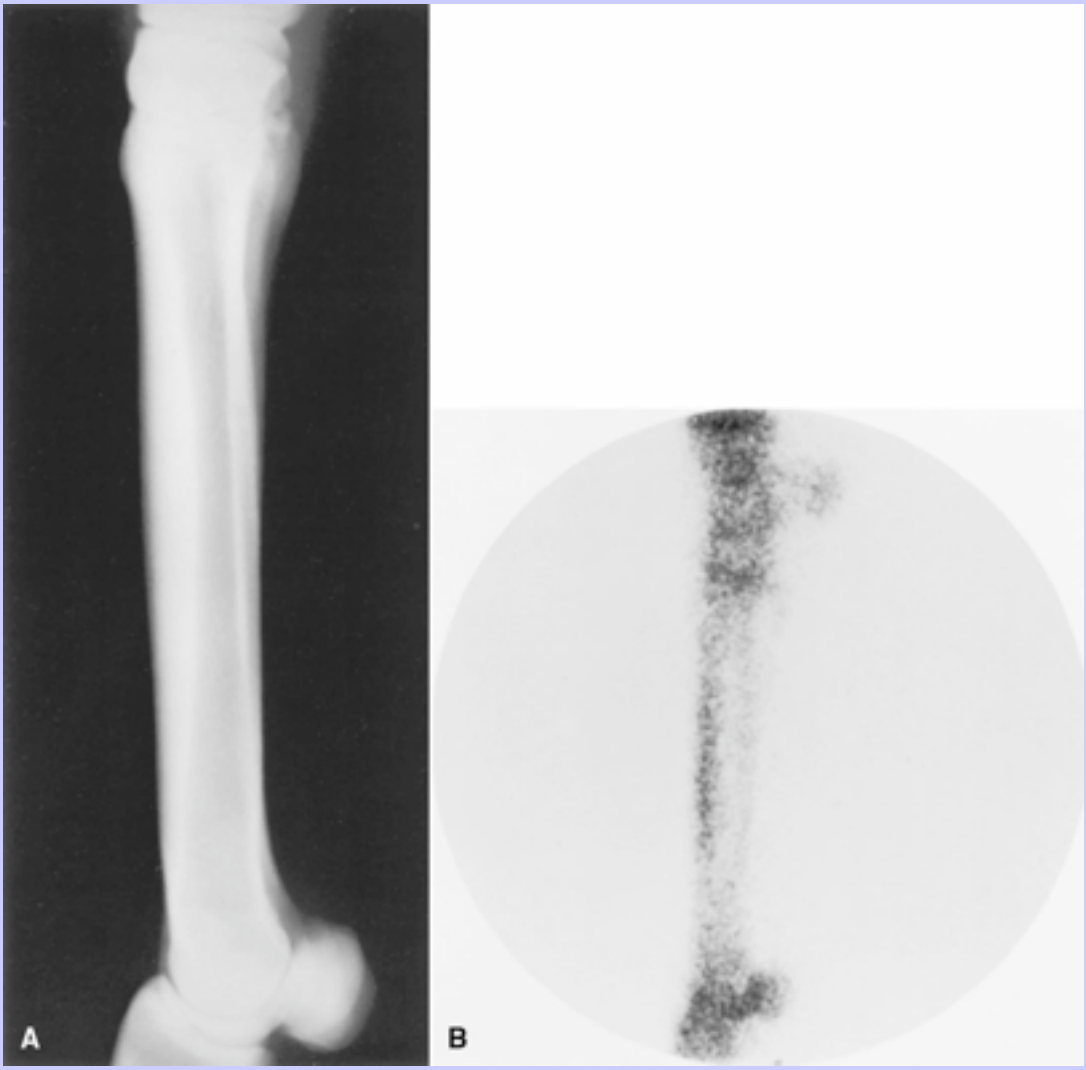
Pain usually was localized to the dorsal aspect of the middiaphysis or near the junction of the proximal and middle thirds of the diaphysis. Initially, pain was mild and elicited from a diffuse area. With continued training, soft tissue thickness became palpable, and diffuse swelling became visible on the dorsum of the metacarpus. Later, soft tissue thickness and swelling became more focal unless hard work was continued. Approximately 2 to 3 weeks after pain first was detectable, discrete hard swellings could be palpated on the dorsum of the metacarpus. Radiographic abnormalities often are absent in horses with acute bucked shins.[412] The dorsal cortex thickens during adaptation to the stresses associated with training,[413] but indistinct periosteal proliferation, subperiosteal demineralization,[412] or subperiosteal radiolucencies support a diagnosis of bucked shins. Even in the absence of radiographic abnormalities, bone scintigraphy demonstrates a diffuse region of intense radiopharmaceutical uptake in the dorsal cortex of affected horses[414] (Fig. 38-43).

Differential diagnoses include cellulitis, periostitis, and osteitis of traumatic or infectious origin, although these conditions are much less common in the racehorse population. Signs of external trauma or infection (e.g., elevated temperature, wound drainage) may be present with these other conditions.

Incomplete cortical fractures occur approximately five times more frequently in the left than in the right metacarpus.[411,415] Left metacarpal fractures occur more often in the mid-diaphysis than in the distal diaphysis; however, in one study a large proportion of right metacarpal fractures occurred in the distal diaphysis.[411] Horses with incomplete cortical fractures are more likely to be examined because of lameness of the affected leg(s) than horses with bucked shins. Lameness, which may be marked after activity, usually subsides within a few days.[415,416] With chronicity a discrete, hard tissue enlargement is visible and palpable overlying the fracture. Focal pain usually can be elicited by digital palpation of the enlargement.

Incomplete cortical fractures may be detected radiographically; however, not all fractures can be visualized. Fracture lines usually extend in a proximopalmar direction from the periosteal surface of the dorsal cortex at a 30- to 45-degree angle to the dorsal cortical surface (Fig. 38-44, *A*). Occasionally, fractures extend in a distopalmar direction from the periosteal surface, and less frequently a saucer-shaped fragment is noted within the dorsal cortex. Fractures rarely appear to course completely to the endosteal surface of the dorsal cortex. In the absence of a radiolucent fracture line, a localized periosteal or endosteal reaction is highly indicative of an incomplete cortical fracture. Alternatively, occult fractures may be identified with bone scintigraphy by intense focal accumulation of radiopharmaceutical[414] (Fig. 38-44, *B*).

Fig. 38-43 **A,** Lateromedial radiograph, and **B,** lateral scintigram, of the third metacarpal bone of a horse with bucked shins. Although dorsal cortical thickening is present, distinct radiographic changes associated with acute metacarpal disease cannot be detected. However, diffuse exaggerated radiopharmaceutical uptake is demonstrated in the dorsal cortex. *Courtesy P.D. Koblik.*



Differential diagnoses for stress fractures include traumatic periostitis or osteitis and osteomyelitis. Radiographic findings and clinical signs of external trauma are helpful diagnostically.

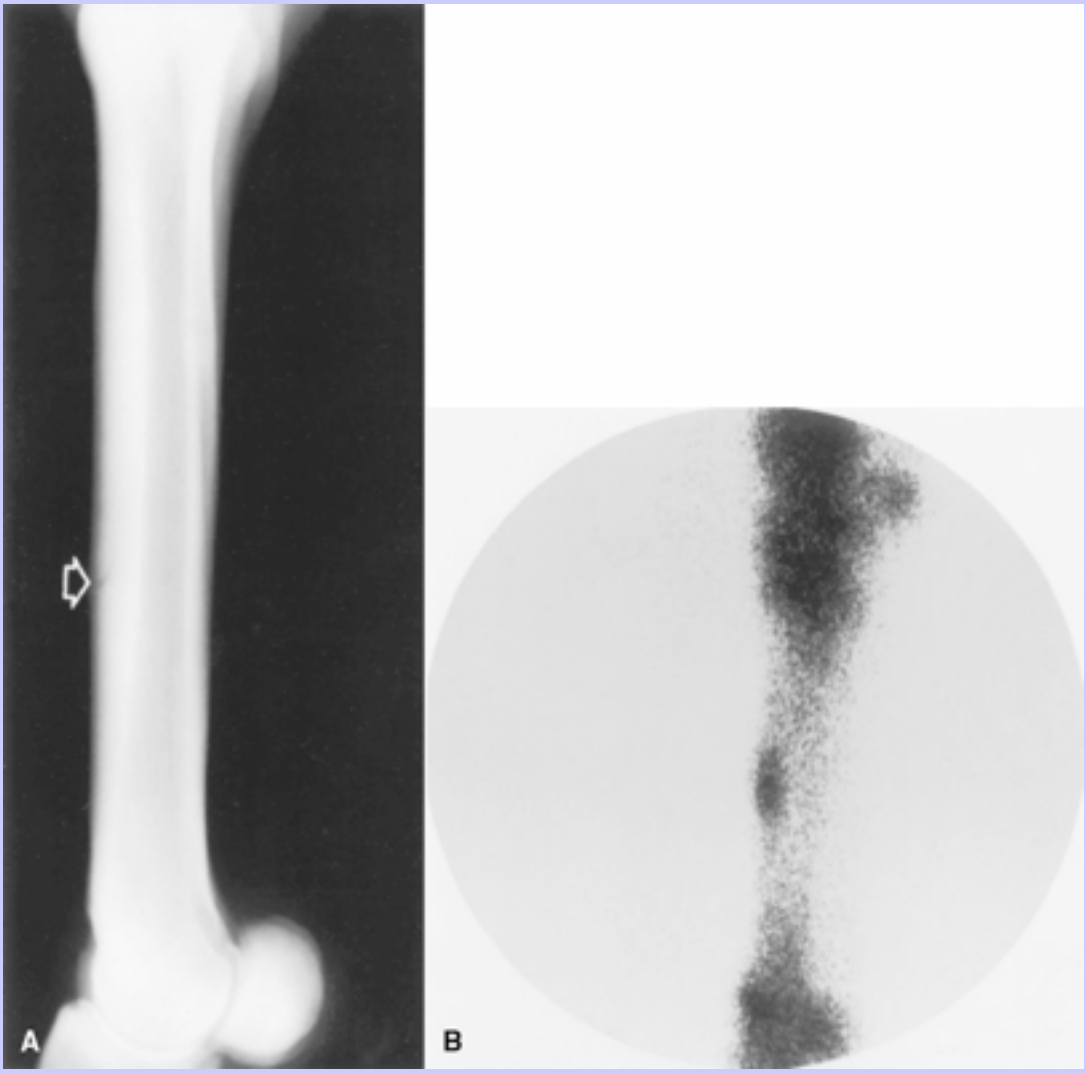
38.17.41.3 Pathophysiology

Bucked shins are believed to result from cumulative microscopic damage within the dorsal cortex of the third metacarpal bone. Microdamage results from excessive strain (i.e., deformation) of young, developing metacarpal bones during training at fast speeds on hard surfaces.

Although third metacarpal bones of 2- to 3-year-old horses have attained adult length, the bone continues to adapt to the increased stresses of race training by enlarging in diameter and replacing intracortical bone through internal remodeling. These processes strengthen the metacarpal bone by increasing its resistance to deformation, decreasing its susceptibility to microdamage with repeated loading, and repairing microdamage. Adaptation usually is completed by 3 to 4 years of age and accounts for the lower incidence of bucked shins and stress fractures in older horses.

If accumulated microdamage with continued training exceeds adaptive and remodeling processes of the metacarpal cortex, bucked shins or chronically incomplete cortical fracture may become clinically and radiographically evident. Because fractures result from accumulation of damage caused by repetitive loading, they are often referred to as “fatigue” fractures. Evidence indicates that the direction of maximum strain on the surface of metacarpal bones changes with a shift from training to racing gaits.[417] Because bone adapts by responding to the magnitude and direction of strain encountered, adaptation during training (i.e., trot and slow gallop) is probably different from that occurring during racing (i.e., racing gallop). Thus, metacarpal bones that have adapted to training may not adapt well to the strains of racing and may incur significant microdamage during initial exercise at racing speeds.[413]

Fig. 38-44 **A,** Lateromedial radiograph, and **B,** lateral scintigram, of the third metacarpal bone of a horse with an incomplete cortical fracture *(arrow)* associated with focal, intense radiopharmaceutical uptake. *Courtesy P.D. Koblik.*



38.17.41.4 Epidemiology

The incidence of bucked shins in 2-year-old thoroughbred racehorses is approximately 70%,[415] occurring most often during the first year of race training. With continued training, horses with cortical microdamage develop stress fractures, which are most common in 3-year-old horses.

The incidence of bucked shins and stress fractures is lower in quarter horse and standardbred racehorses than in thoroughbreds. The high incidence in thoroughbred horses may be associated with running long distances at the racing gallop.[418] Thoroughbred horses are subjected to more high-stress loading cycles than quarter horses running shorter distances or than standardbred horses trotting or pacing. Therefore, thoroughbred horses are more likely to accumulate clinically significant amounts of cortical microdamage.

38.17.41.5 Necropsy Findings

Bucked shins and incomplete cortical fractures may be found incidentally on postmortem examination of racehorses. Callus may be evident on the periosteal surface. Cross sections of the bone may disclose an incomplete cortical fracture or endosteal bony proliferation. Histologic examination usually reveals an indistinct fracture line characterized by marked bone resorption.[419]

38.17.41.6 Treatment and Prognosis

Treatment of bucked shins varies with the degree of pain and the decrease in the performance of affected horses. On palpation, mildly and moderately affected horses exhibit resentfulness and mild soreness, which disappears within 2 to 4 days.[420] Training should be continued, but at a slower pace, to promote continued adaptation of bone to the stress of racing and to prevent the accumulation of additional microdamage. In severely affected horses, pain remains evident after 1 week of rest. These horses may require complete rest for a minimum of 3 months before they can be returned to training. After a horse has recovered from bucked shins, the prognosis is good for return to training, although the condition will recur in severely affected horses that were not rested for long enough before their return to training and in horses whose exercise intensity was accelerated too rapidly on return to training.

Many adjunctive therapies, including pin firing, cold therapy, and electrostimulation, also are frequently used. Their effectiveness, however, is difficult to assess without considering concurrent training or rest therapy. Horses with incomplete cortical fractures must be rested for a minimum of 3 to 6 months. Most rested horses show radiographic evidence of bone healing and can be returned to training. Some chronic fractures are refractory to rest alone. Occasionally, returning these horses to light exercise stimulates fracture healing. Alternatively, interfragmentary drilling has resulted in better healing of fractures with fewer adverse effects than lag screw fixation. After interfragmentary drilling and adequate rest (e.g., 3 to 6 months), the prognosis is good for return to racing. Without an apparent relationship to type of treatment, however, incomplete fracture recurs in some horses.

38.17.41.7 Prevention

Factors in the prevention of bucked shins and stress fractures include training regimen, racetrack surface, and shoeing. In general, a training program should gradually increase the degree of exercise, allowing time for concurrent bone adaptation, and should subject the metacarpus to similar strains encountered during racing.[413] Experimental evidence suggests that the metacarpus would have to encounter the strain associated with racing stress only for short duration a few times per week to stimulate the appropriate adaptive response.[421] The effect of exercise on bone adaptation and remodeling is under active investigation. Hard racetrack surfaces are associated with a higher incidence of bucked shins than softer surfaces.[422] The stresses and

strains incurred by the metacarpus probably can be modified by changing the character of the racing surface or the horseshoe.

39 Chapter 39 Diseases of the Eye

Consulting Editors

David J. MagGs

39.1 OPHTHALMIC HISTORY AND EXAMINATION

CECIL P. MOORE

ERIN S. CHAMPAGNE

Before pursuing a detailed ophthalmic history, it is imperative to document the species, breed, age, gender, coat color, and use of the animal(s) to be examined and to obtain a general medical history. Because ophthalmic diseases of large animals may be genetic, an awareness of breed-related ocular abnormalities is also important.

The primary complaints of the owner regarding the animal's eye(s) or vision may generally be categorized into one of the following areas of concern:

- Abnormal appearance of one or both eyes (i.e., asymmetry or color change)
- Presence of ocular discharge
- Presence of ocular pain
- Reduced vision or blindness

Additional reasons for obtaining a thorough ophthalmic history and performing a detailed ocular examination are to follow up on a preexisting or previously treated eye condition or to examine the eyes as part of a prepurchase examination. Examinations for inherited eye diseases in horses may be performed by board-certified veterinary ophthalmologists and registration forms submitted to the Equine Eye Registration Foundation.[1]

39.2 OPHTHALMIC HISTORY

A series of questions should be directed to the owner or responsible person regarding the signs observed, the duration and clinical course of the condition, the animal's ability to function in its normal environment, the existence of previous eye problems, and whether related animals or other animals on the premises have been affected. Potential causes for an ophthalmic or visual problem, including any possible relationship to neurologic or iatrogenic (e.g., drug-induced) disease, toxin exposure, or systemic illness, should be explored. To ensure that the necessary questions are asked in a reasonable sequence, a history form is suggested (Fig. 39-1).

39.3 OPHTHALMIC EXAMINATION PROCEDURES

39.3.1 General Inspection

It is optimal to observe the animal's activities and movements in its normal environment. Before restraining the animal, the examiner should study the animal's unencumbered movements, posture, coordination, and head

carriage. During this initial inspection, the animal's vision and its response to visual stimuli should also be observed.

As the animal is approached, closer inspection reveals whether facial and ocular symmetry and normal eye movements are present. Signs of ocular pain (i.e., blepharospasm, apparent photophobia, or epiphora) are noted, as well as size and position of the globes and the presence of ocular or nasal discharge, opacities, or masses.

39.3.2 Restraint

Adequate restraint is an essential prerequisite to performing a detailed ophthalmic examination in large animals. Manual restraint of small ruminants and neonates is usually adequate. For most cattle, restraint with a chute, head catch, and halter is essential; restraining the horse with a halter in stocks is recommended. However, chemical restraint may be necessary in cattle and is almost always needed for horses before a thorough examination can be performed. This may consist of a combination of injectable sedative (e.g., xylazine or detomidine for horses), with or without an injectable analgesic (e.g., butorphanol for horses), with auriculopalpebral (and occasionally frontal) nerve blocks using a local anesthetic agent such as 2% lidocaine. A neuroophthalmic assessment, including menace responses and palpebral/pupillary light reflexes, should be done before administration of sedatives, analgesics, or local anesthetics.

39.3.3 Neuroophthalmic Assessment

An evaluation of the integrity of cranial nerves associated with normal ocular function is conducted (see Chapter 8). This includes a rapid assessment aimed at determining the animal's ability to do the following:

- Perceive tactile stimuli of the facial and ocular surfaces
- Blink effectively with complete eyelid closure
- Move and position the eyes normally
- Constrict or dilate pupils in response to background and focal illumination
- Respond to visual stimuli such as hand motions or moving objects

39.3.4 Instruments and Materials

After a general inspection, restraint, and neuroophthalmic assessment, a detailed ophthalmic examination is performed. A few basic instruments and materials facilitate an efficient and thorough examination. These include a focused light source (a 3.5-V halogen rechargeable light source with a Finoff transilluminator is preferred), a direct ophthalmoscope, magnifying loupes, and thumb forceps (blunt-tipped forceps with shallow serrations are recommended). Sterile fluorescein dye strips, tear test strips, culture swabs, physiologic saline solution (flushing solution), topical anesthetic (0.5% proparacaine), and mydriatic solution (1% tropicamide) are often also necessary. For irrigating nasolacrimal ducts, polyethylene tubing (5 French) should be available.

OPHTHALMOLOGY HISTORY

Case Number _____

Species _____ Breed _____

Color _____ Sex _____ Age _____

Name or identification _____

Owner's name _____

Address _____

Telephone _____

1. What led you to believe your animal has an eye problem?
   - ☐ Loss of vision
   - ☐ Eye discharge
   - ☐ Abnormal appearance
   - ☐ Ocular pain
   - ☐ Veterinarian noted problem
   - ☐ Other (explain, i.e., observed injury) _____

2. How long has this problem been present? _____

3. Which eye(s) is(are) affected? RIGHT LEFT BOTH

4. Has the character of the eye(s) changed since you first noticed it? NO YES UNKNOWN
   If YES, how? _____

5. Have the eyes been treated? NO YES
   If YES, how, and with what? _____

6. How well do you believe your animal sees?
   - ☐ Excellent
   - ☐ Poor on all occasions
   - ☐ Poor especially in dim light or dark
   - ☐ Poor especially in bright light
   - ☐ Poor in regard to near objects
   - ☐ Poor in regard to far objects
   - ☐ Poor in regard to moving objects
   - ☐ Poor in regard to stationary objects
   - ☐ Poor when turning to the right
   - ☐ Poor when turning to the left
   - ☐ Poor when jumping or climbing down
   - ☐ Poor when jumping or climbing up

7. Do you think your animal sees well in familiar surroundings? YES NO UNKNOWN
   Strange surroundings? YES NO UNKNOWN

8. Has your animal had any other eye problems? NO YES UNKNOWN
   If YES, what type? NO YES

9. Has your animal experienced seizures, loss of balance, weakness, incoordination, or personality change? NO YES UNKNOWN

10. Is your animal receiving medication? NO YES
    If YES, what? _____

11. Do you have other animals? NO YES
    If YES, do they have eye problems? NO YES
    If YES, what type? _____

12. Do you know your animal's dam, sire, or other related animals? NO YES
    If YES, do any of them have eye problems? NO YES UNKNOWN

13. Has your animal been exposed to house or farm chemicals (cleaners, agricultural, industrial, or automotive chemicals) or building supplies? NO YES UNKNOWN

14. Has your animal had previous or present illness? NO YES UNKNOWN
    If YES, what type? _____

15. Is your animal consuming water and food normally? YES NO UNKNOWN

16. Is your animal urinating more frequently than normal? NO YES UNKNOWN

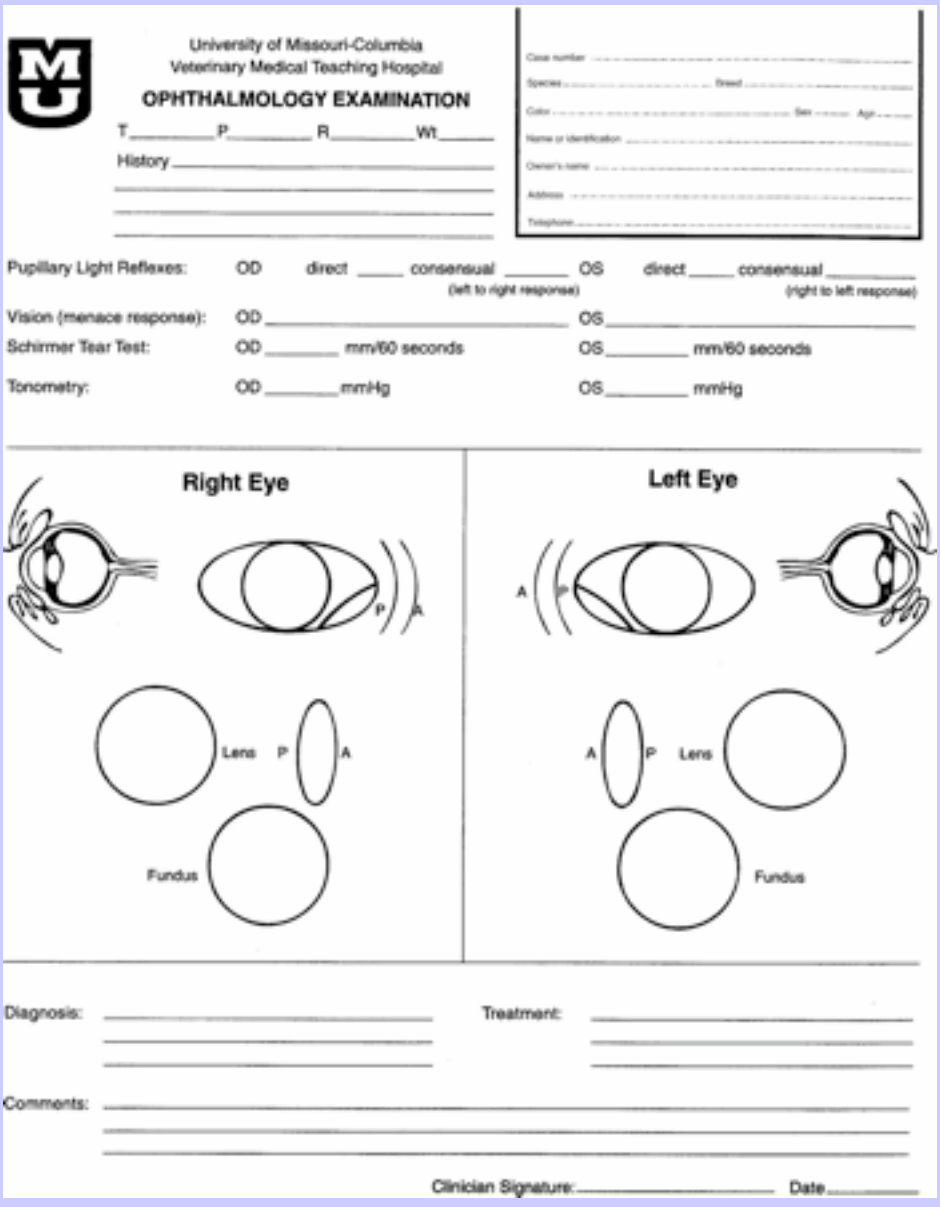
39.3.5 Detailed Examination

For recording results of the ophthalmic examination, use of a standard form is recommended (Fig. 39-2). The detailed examination begins with palpation of the boundaries of orbit for irregularities, asymmetry, masses, or fractures. Next, the globe is retropulsed to assess for increased resistance (indicating a space-occupying mass) and to inspect the anterior aspect of the nictitating membrane ("third eyelid"). Retropulsion should not be done if the cornea is compromised by a deep ulcer or laceration.

1261

1262

Fig. 39-2 Use of an ophthalmologic examination form allows the clinician to perform a complete, systematic ocular examination.



At this point, the examiner determines if ocular cultures or tear measurements are desired, because these procedures must be completed before further manipulations are performed and before topical pharmacologic agents are instilled.[2] Depending on the clinical signs, severity of ocular disease, and species being examined, viral, bacterial (e.g., *Chlamydia, Mycoplasma*), or fungal cultures may be indicated. Sterile swabs moistened with saline and appropriate enrichment broth or transport media are applied to the tissue to be cultured (usually cornea or conjunctiva). The moistened tip is placed in direct contact with the tissue surface and the swab rotated by spinning the end of the stem with the fingertips.

The rest of the ophthalmic examination is performed in a darkened area, initiated by directing a focused light through each pupil to establish the presence of a fundus reflex (light reflected from back of eye that normally fills pupil space). By evaluating the fundus reflex in each eye, the examiner may compare pupil sizes, characterize pupillary light reflexes, and assess clarity of the ocular media.

Examination of ocular structures should be performed in a set pattern (i.e., anterior to posterior).[3–6] Use of an ophthalmic examination form is helpful in systematically guiding the clinician through the examination and providing a record of examination findings (see Fig. 39-2).

The eyelids are inspected for integrity, position, and movement. Each lid is digitally everted for inspection of the margins, meibomian gland openings, and palpebral conjunctiva. Paresis, malposition (entropion, ectropion), defects, masses, inflammation (swelling, ulceration, exudates), alopecia, foreign bodies, and abnormal lashes are noted.

The nictitating membranes are examined for normal position, integrity of surfaces and margin, degree of pigmentation, and the presence of follicles or masses. To inspect for foreign bodies possibly concealed by the third eyelid, topical anesthetic solution (0.5% proparacaine) is instilled repeatedly onto the ocular surface. Two drops every 20 to 30 seconds for four applications is generally adequate. After topical anesthesia is applied, the nictitating membrane is grasped and manipulated with blunt-tipped, slightly serrated thumb forceps, and both sides are examined for foreign bodies.

Normally the conjunctiva appears moist, glistening, and semitransparent. Signs of conjunctivitis are chemosis (conjunctival edema), hyperemia, and ocular discharge. Color changes of the conjunctiva usually accompany anemia (blanched, pale) or icterus (yellow, amber). Chemosis may indicate severe hypoproteinemia. Conjunctival lesions noted include focal swellings, follicles, adhesions, or masses. The sclera underlying the bulbar conjunctiva is inspected for color, contour, swellings, masses, pigmented areas, or surface irregularities.

The avascular cornea should be smoothly contoured and transparent with a moist, reflective surface. The cornea is examined for irregularities and opacities and for the presence of blood vessels and melanin. Corneal edema appears as a hazy blue corneal opacity and should be characterized as localized or diffuse. With severe corneal edema, the epithelial surface may bulge and bullae (vesicles) may be noted. With corneal suppuration and necrosis, the cornea becomes more densely opaque and acquires a beige, green, or milky appearance. Infectious keratitis is characterized by suppuration and necrosis. Corneal abscesses occur as focal areas of suppuration within the stroma underlying a nonulcerated cornea.

Corneal opacities may also result from focal or diffuse scarring, areas of corneal degeneration or dystrophy, or stretching of Descemet's membrane from previous elevation of intraocular pressure or previous trauma. Inflammatory products clustered on the corneal endothelium (keratic precipitates) appear as multiple beige or brown foci, usually on the ventral aspect of the corneal endothelial surface. This finding indicates the presence of anterior uveitis.

Lacrimal system examination entails evaluation of both secretory and excretory components. Normal secretions result in a moist, glistening ocular surface. Although not typically performed in large animals, tear test strips may be used to quantify the volume of aqueous tear secretion (see Ancillary Diagnostic Procedures). To examine the excretory components, the upper and lower puncta and nasal openings of the nasolacrimal system are identified. Any overflow of tears onto the face (epiphora) is noted. Causes of increased ocular secretions (e.g., frictional irritants, foreign bodies, corneal ulcers, ocular inflammation) must be ruled out. Causes for stimulation of lacrimal secretions must be differentiated from causes of outflow occlusion, such as congenital atresia and acquired obstruction of the nasolacrimal system.

Fluorescein dye instillation determines if corneal ulceration is present and aids in assessment of nasolacrimal system patency. Passage of dye from the nasal opening of the nasolacrimal duct within 5 minutes confirms patency. Retrograde irrigation of the nasolacrimal duct by inserting a length of 5-Fr flexible tubing into the nasal punctum and flushing with physiologic saline solution may be necessary to differentiate insufficient drainage from excessive secretions.

Intraocular examination begins with evaluation of the clarity and depth of the anterior chamber. Opacities within the anterior chamber include inflammatory products (cells and fibrin), proteins (flare), red blood cells (hyphema), or white blood cells (hypopyon). Suspended or clustered inflammatory materials in the anterior chamber indicate intraocular inflammation (anterior uveitis). Besides the presence of exudates, loss of anterior chamber transparency may result from lens luxation, anterior synechia, or intraocular masses (neoplasia or foreign bodies). Loss of normal anterior chamber depth may result from flattening of the cornea, leakage of aqueous humor, staphyloma formation (protrusion of uvea through the cornea), iris bombé (forward bulging of the iris caused by iris-lens adhesions), or forward displacement of the lens. Increased depth of the anterior chamber may be caused by a protruding cornea (keratoconus) or posterior displacement of the iris or lens.

The iris is inspected for altered contour, pigmentation, mobility, neovascularization, pupil size and shape, and the presence of iridal masses (including the normal granula iridica). Transillumination of iris masses allows differentiation of solid iridal masses (e.g., melanoma) from iris cysts. In animals with lightly colored or spotted hair coats, multicolored irides should be recognized as normal variants. Although uncommon, congenital iris thinning (hypoplasia) may be noted as dark, flat, or translucent areas. The lens-iris interface is best evaluated when the pupil is dilated. Iris membranes, adhesions, or strands should be characterized as congenital (persistent pupillary membranes) or acquired (synechiae or remnants of iris atrophy).

Pupillary openings are evaluated for size, shape, symmetry, movements, and opacities. Direct and indirect (consensual) pupillary light reflexes are assessed. The examiner must recall that pupillary light reflexes are not a test of vision (i.e., abnormal responses may be observed in visual animals, and normal reflexes may occur in nonvisual animals). Pupillary abnormalities that should be noted are inequality in size (anisocoria), abnormal movements (hippus), abnormal location (corectopia), or abnormal shape (dyscoria). 1262 1263

Opacities of the pupil usually result from loss of lens transparency or from presence of intraocular exudates. Obscuration of the pupil space may occur with severe miosis (from acute anterior uveitis), condensation of anterior chamber exudates, or synechiae formation (from chronic uveitis). In animals with normal pupillary light reflexes, complete examination of the lens and structures posterior to the lens (i.e., vitreous and fundus) may be achieved only after dilation with a mydriatic agent such as 1% tropicamide, which usually occurs 20 to 30 minutes after instillation.

Using a focused light, the lens is inspected for a smooth, transparent, convex anterior capsule and normal position (no part of the equator should be visible). When evaluating for lens opacities (cataracts), the examiner

should direct the focused light through the axial part of the lens to establish the presence of a fundus reflex. Cataracts may be classified according to the extent to which a fundus reflex occurs; a *partial* reflex indicates an incomplete cataract, whereas an *absent* reflex indicates a complete cataract). Focal cataractous changes are observed as dark areas seen within the area of reflected light.

An ophthalmoscope must be used to examine the vitreous and fundus. Using the monocular direct ophthalmoscope, the vitreous should be in focus with a dioptric setting between +6 to +1, and the fundus is usually in focus between +1 and −2 diopters. The vitreous is examined for congenital remnants (retained hyaloid structures) and opacities, including degenerative materials or exudates.

Examination of the fundus begins with identifying the optic disc (papilla) and studying its size and shape. The shape, location, and vascular pattern of the optic disc and the appearance of the fundus vary considerably among species. In ruminants the optic disc margin typically appears irregular and fluffy, indicating myelination of axons entering the optic disc. However, it tends to be horizontally elliptical or kidney shaped and located in the tapetal portion of the fundus.[4] An optic disc with extensive myelination may be elevated above the surface of the fundus (sometimes called *pseudopapilledema*). In ruminants the major retinal arterioles are large and are accompanied by venules that anastomose on the surface of the optic disc. The dorsal arteriole and venule usually intertwine as they course away from the disc over the midtapetum (Fig. 39-3). By contrast, the equine fundus is characterized by a large, pink or salmon-colored, horizontally elliptical or oval disc located in the nontapetum[5] (Fig. 39-4). In equidae, multiple small retinal blood vessels extend radially from the margin of the disc, and no anastomotic venules are visible over the optic disc.

In both ruminants and horses the fibrous tapetum is penetrated by choroidal capillaries; thus the fundus in these species is typified by dark, stippled foci termed *stars of Winslow*. Coloration of the tapeta of large animals also varies considerably and may range from gold to bluish green. In animals with heterochromia irides, areas of the fundi may characteristically be devoid of pigmentation and may lack a tapetum. These areas may appear orange or red because of direct visualization of the choroidal vasculature.

Abnormalities of the optic disc include hypoplasia (micropapilla), elevation (papilledema), depression (cupping), degeneration (atrophy; Fig. 39-5), and vascular changes (e.g., congestion, attenuation, hemorrhage). The tapetal fundus is evaluated for clarity, coloration, pigmentation (Fig. 39-6), and integrity of the retinal vessels (Fig. 39-7). The nontapetal fundus is evaluated for uniformity of pigmentation. Both tapetal and nontapetal areas are assessed for retinal elevations or separations (Fig. 39-8), hemorrhages, degenerations, disorganization (dysplasia), or scleral defects (colobomas).

Fig. 39-3 Normal ruminant fundus characterized by a large, kidney-shaped, myelinated optic disc. Note that the large retinal arteriole and venule intertwine as they course dorsally.

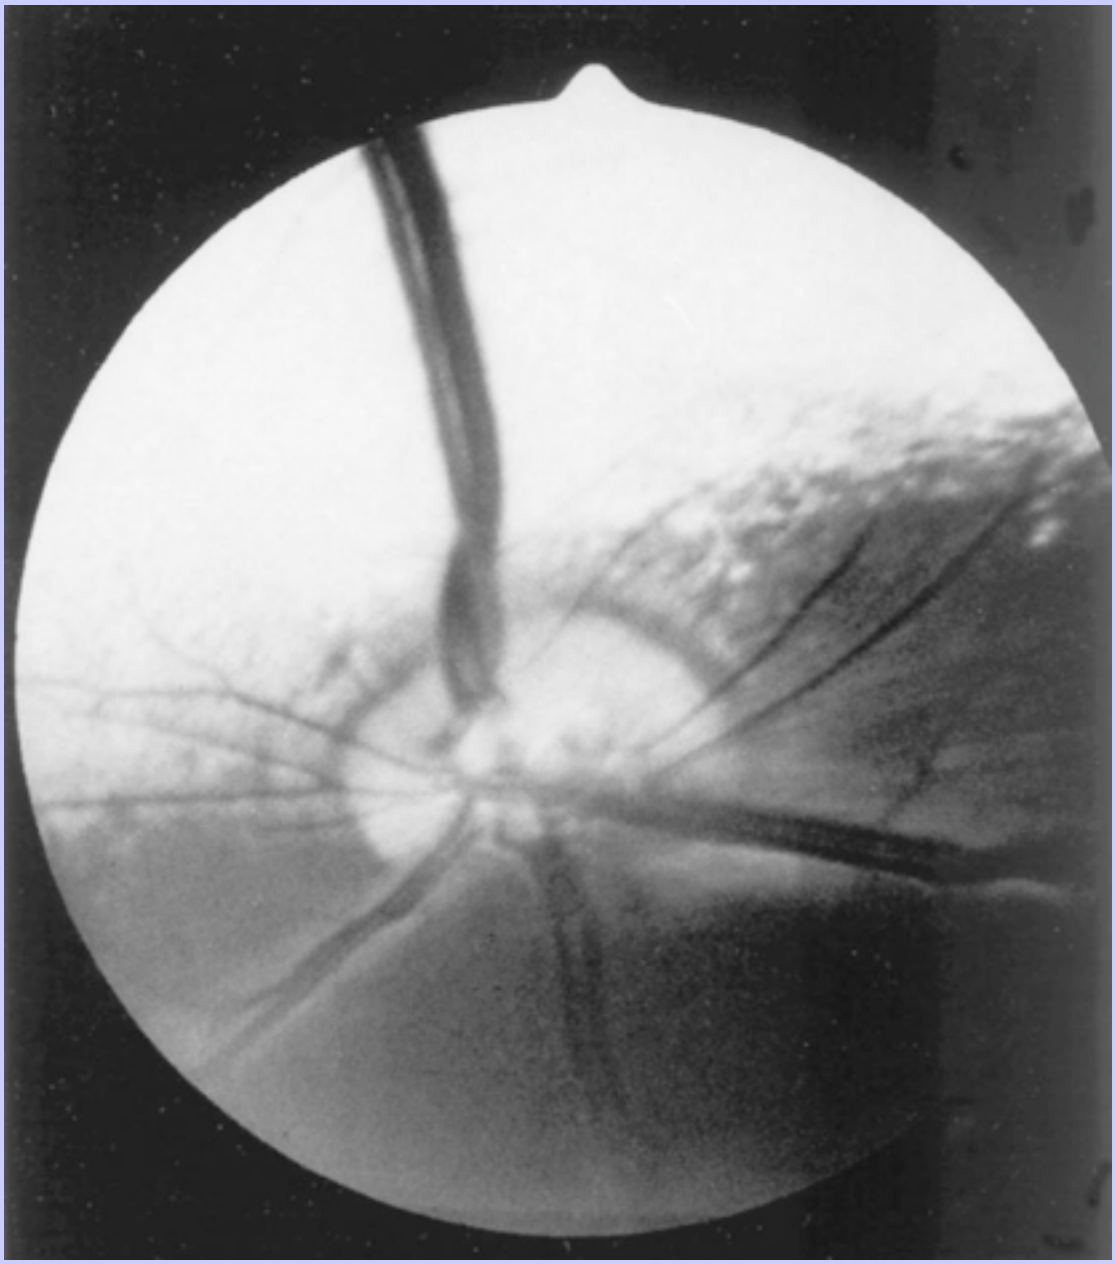


Fig. 39-4 Normal equine fundus characterized by a large horizontally elliptical optic disc with numerous small retinal vessels entering (arterioles) and exiting (venules) the margin of the optic disc. Note that the optic disc lies in the nontapetal portion of the fundus.

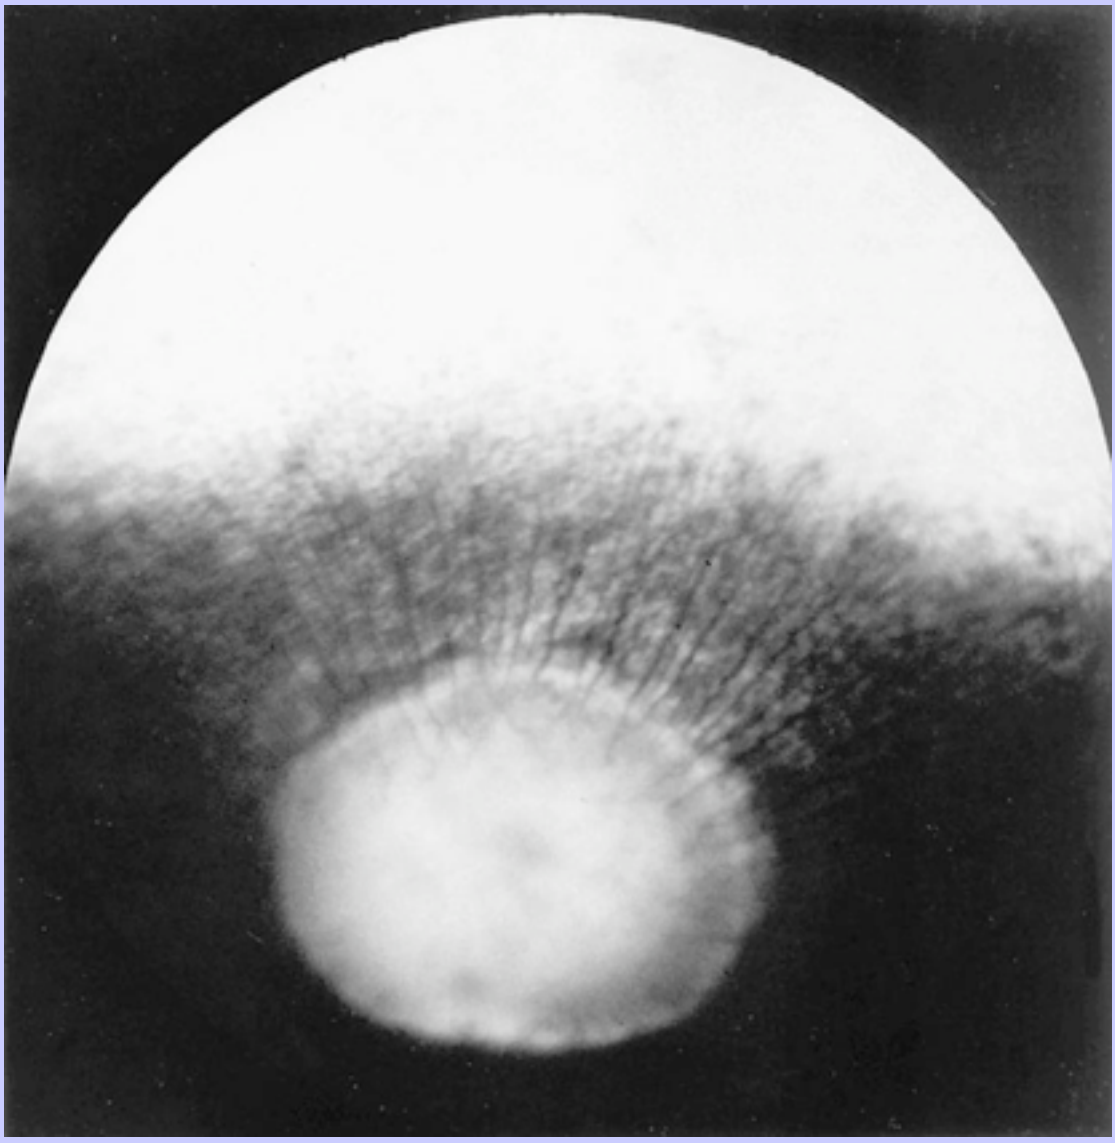

39.4 ANCILLARY DIAGNOSTIC PROCEDURES

Several additional procedures may form important supplements to the complete ophthalmic examination. Although some ancillary procedures require specialized equipment and expertise, many may be performed in general practice.

Fig. 39-5 Optic nerve atrophy (equine). The margin of the disc is quite distinct because of myelin loss, which is characteristic of optic nerve atrophy. Note absence of retinal blood vessels.

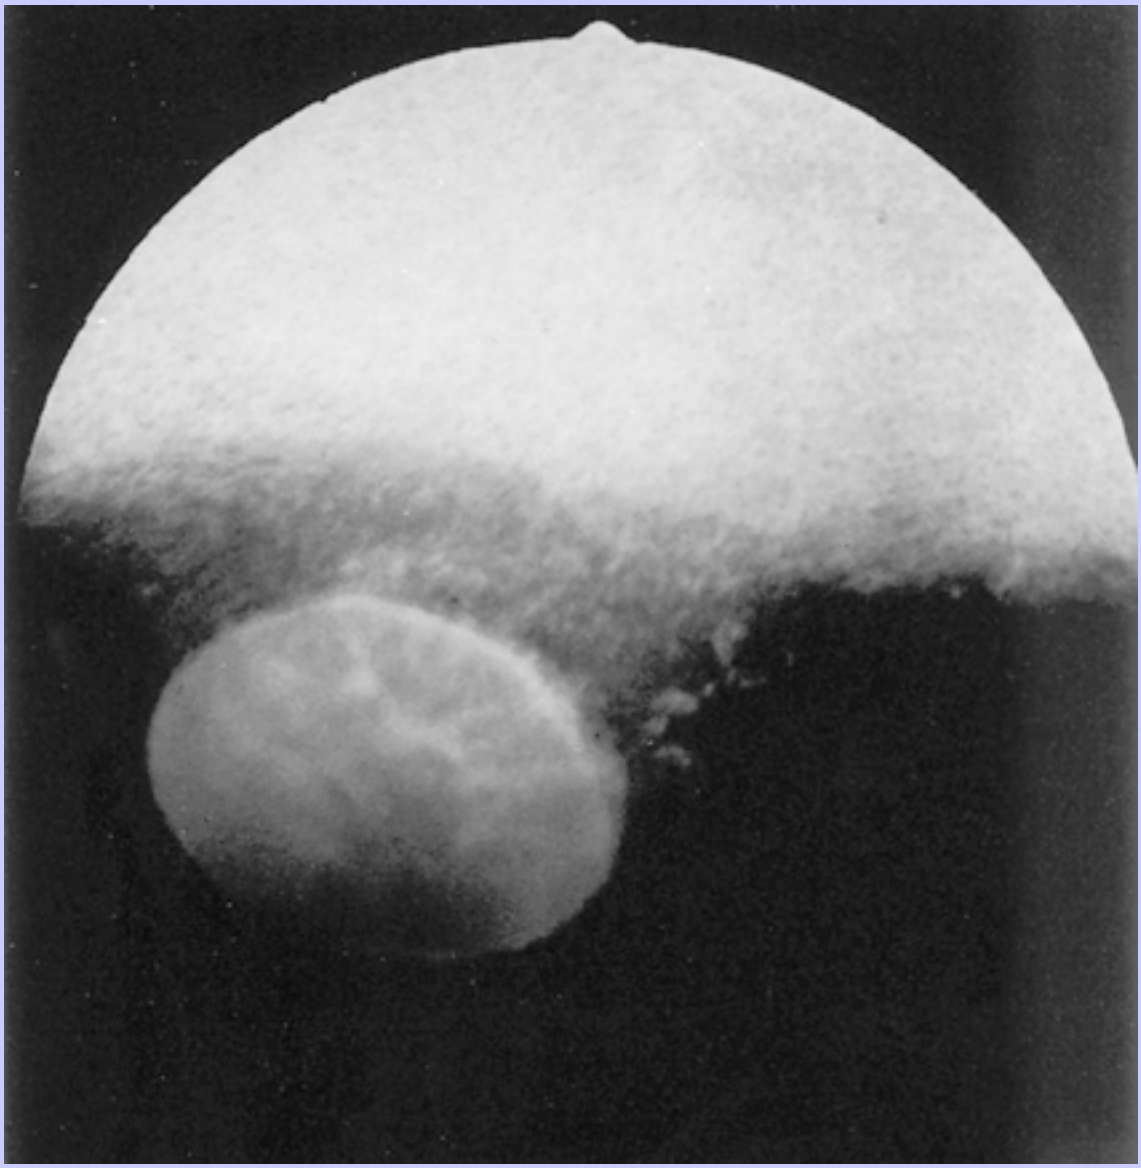

Fig. 39-6 Pigmentary changes after traumatic chorioretinopathy. Irregular linear areas of hypopigmentation and hyperpigmentation are present in the tapetal fundus of a horse after ocular trauma. Pigmentary changes reflect retinal pigment epithelial disturbance from previous hemorrhage and edema. *Courtesy Dr. K.N. Gelatt*.

Fluorescein and rose bengal are ocular surface stains most often used as aids in diagnosing conjunctival and corneal diseases. The tip of a sterile dye-strip is moistened with saline or eye-irrigating solution, and a drop of the stain is instilled onto the eye. Fluorescein is a water-soluble dye used to detect exposed corneal stroma resulting from an epithelial defect (erosion), stromal ulceration, or descemetocele. The pattern of fluorescein staining for a

descemetocele is characterized by a donut-shaped area of positive fluorescence, with the perimeter retaining stain and the center or deepest area (Descemet's membrane) not retaining stain. Fluorescein may also be used to evaluate the patency of nasolacrimal ducts because an open duct allows the transmission of stain, which may be observed exiting the duct system at the nasal orifice. Rose bengal is retained by devitalized surface cells and is 1264
therefore useful in detection of subtle abnormalities such as hyperplastic or desquamating cells associated with 1265
ocular surface drying, herpetic infection, or squamous cell carcinoma.

Fig. 39-7 Retinal degeneration (bovine). Peripheral retinal vessels are greatly attenuated near the tapetal-nontapetal junction. The attenuation is accompanied by hyper-reflectivity of the tapetal region. These changes are consistent with generalized retinal atrophy.

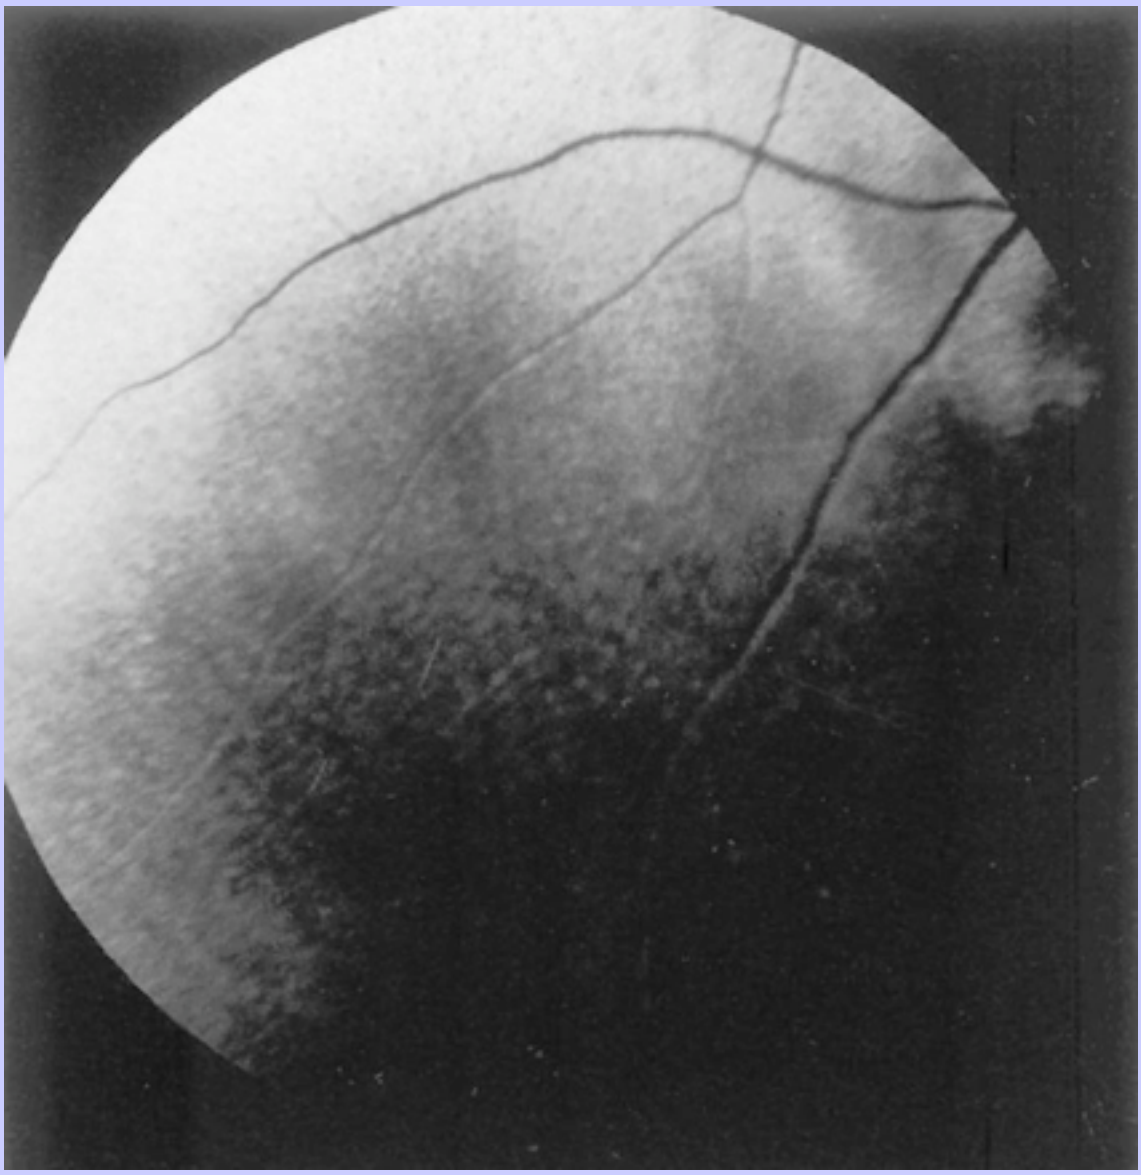

Fig. 39-8 Retinal separation (equine). Gray, linear areas radiate from the optic disc into the nontapetal region of the fundus. Note that the margin of the disc is quite indistinct in the affected area. An absence of retinal vessels indicates concurrent retinal degeneration.

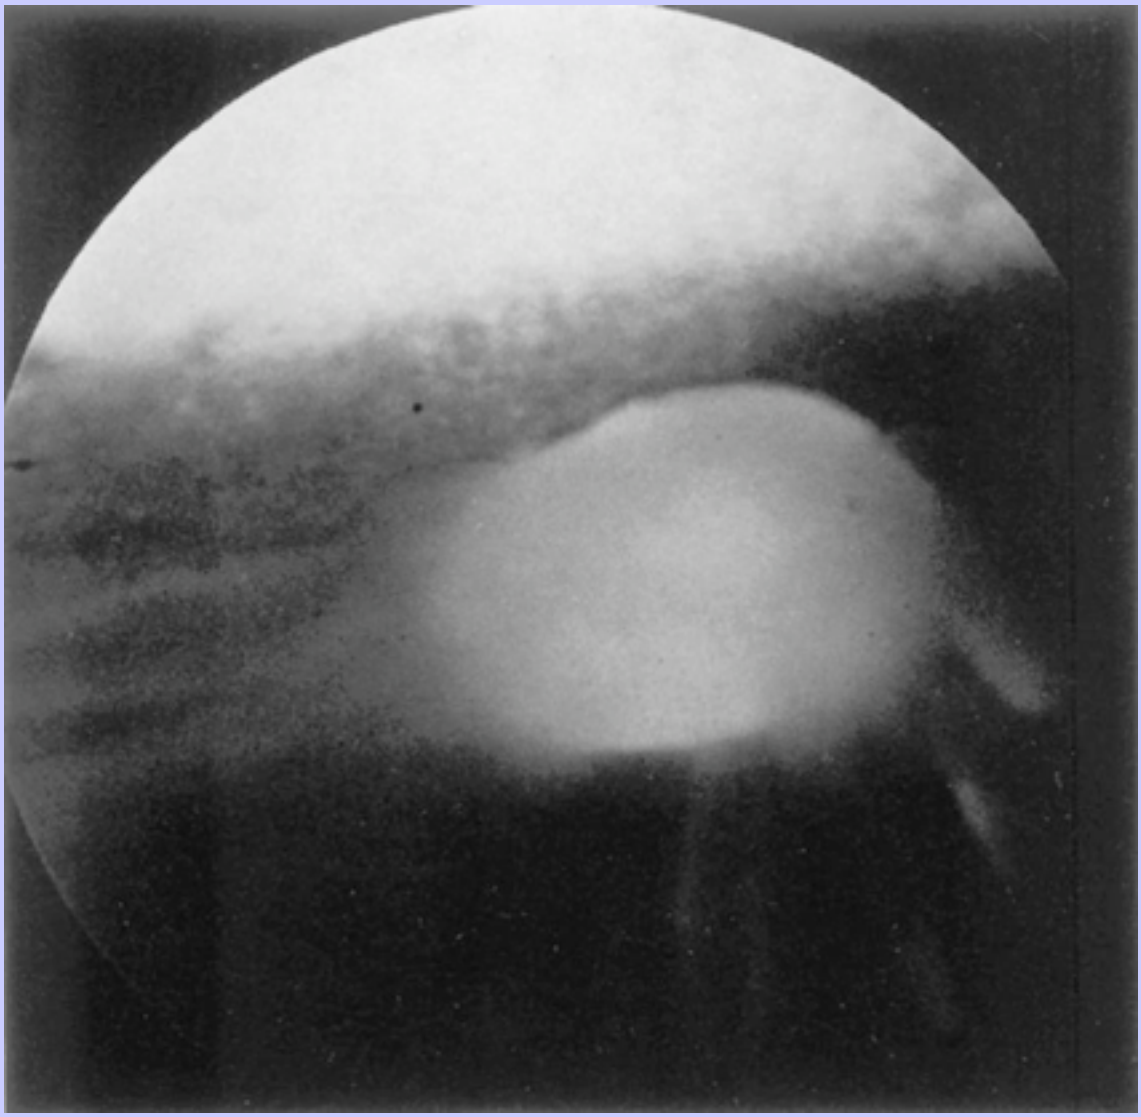

Although tear deficiencies are uncommon in large animals, tear test strips may be beneficial to quantify aqueous tear production in selected cases. A sterile filter paper strip (40 × 5 mm with notched end) is inserted into the lower conjunctival fornix. In large animals it is sufficient to measure the amount of wetting in 30 seconds (≥20 mm is normal).

Cytologic evaluation of ocular surface scrapings or intraocular aspirates may differentiate between inflammatory and neoplastic diseases or in some cases may provide a definitive diagnosis. Orbital aspirates may be diagnostic in

cases of exophthalmos caused by neoplasia (e.g., lymphosarcoma). Immunofluorescent testing of cytologic specimens may confirm viral (e.g., infectious bovine rhinotracheitis) or chlamydial infections.

Bacterial cultures taken from the ocular surface or from ocular aspirates, with subsequent antimicrobial susceptibility testing, may be necessary for definitive diagnosis and appropriate treatment of ocular infections. The diagnostic laboratory performing ocular cultures may offer suggestions on culture procedures, including preferred transport media and handling of samples. It is especially important to consult with the laboratory in advance when anticipating culturing for fungi, *Mycoplasma, Chlamydia,* or viral agents.

Tonometry, a means of measuring the intraocular pressure (IOP), is useful in diagnosing glaucoma (elevated IOP) and uveitis (low IOP) and in assessing response to therapy for these conditions. Digital tonometry (gently indenting the globe through the upper eyelid) provides a general evaluation of IOP, at best characterizing the globe hypotensive, normotensive, or hypertensive. Digital tonometry should not be done if the cornea is compromised by a deep ulcer or laceration. By contrast, applanation tonometry using the Tonopen provides accurate and reproducible IOP readings in large animals and is routinely performed at referral institutions or specialty practices. Schiøtz tonometry is not applicable to large domestic species.

Biomicroscopy, using a portable handheld slit lamp, is useful for identifying the location and nature of anterior ocular opacities. Focal irritants (e.g., ectopic cilia, small foreign bodies) may only be visible with the magnification provided using biomicroscopy. In addition, subtle opacities of the lens and anterior vitreous may only be detected with the use of a slit-lamp biomicroscope.

Funduscopic examination may be performed relatively quickly and easily using the technique of indirect ophthalmoscopy. Monocular indirect ophthalmoscopy is performed using a handheld light source and a separate 20- or 28-diopter focusing lens. Binocular indirect ophthalmoscopy uses a light source mounted on a head band with an incorporated prism and binocular viewing apertures. Binocular indirect ophthalmoscopy provides a stereoscopic, panoramic view of the fundus and is routinely performed by veterinary ophthalmologists. The light sources used for indirect ophthalmoscopy may be adjusted to relatively high intensities and therefore enhance visualization of the fundus through partially opacified or hazy ocular media.

Other ancillary diagnostic procedures include electroretinography, visual-evoked potentials, and imaging procedures (radiography, ultrasonography, computed tomography). Although plain skull radiographs and some contrast studies (e.g., dacryocystorhinography) may be performed in a general practice setting, the remaining procedures require techniques and equipment usually available only at referral centers.

39.5 SIGNS OF OCULAR DISEASE

CECIL P. MOORE

DAVID J. MAGGS

The five major signs of eye disease are as follows:

- Ocular or periocular asymmetry
- Ocular color change
- Ocular discharge
- Ocular pain

- Visual deficits or blindness

Although any one of these signs alone may be the most obvious evidence of ocular disease, they frequently occur in various combinations. This section provides a general description of the signs and examples of ocular diseases in which a particular sign predominates. Table 39-1 summarizes common signs of ocular disease in large animals.

39.6 OCULAR OR PERIOCULAR ASYMMETRY

Ocular or periocular asymmetry results from unilateral changes in anatomy of the orbit, orbital contents, globe, eyelids, or pupils. Such changes often involve reduction or increase in volume of a certain tissue. *Reduction* in tissue volume occurs with congenital hypoplasia, cicatricial shrinkage, atrophy, or dehydration. *Increase* in tissue volume may involve the whole globe (buphthalmos) or be characterized by irregular enlargement, as seen with inflammatory or neoplastic lesions involving the globe, orbit, or lids. Asymmetry may also result from neurologic dysfunction. Common examples include reduced palpebral fissure size (secondary to facial nerve paralysis), strabismus, third eyelid protrusion, and anisocoria (see Chapter 8). This section describes a method of approaching the eye examination and of categorizing lesions noted. It is not the intent to describe in detail each of the diseases that may be noted; these are covered in other sections of this chapter.

Forward displacement of the eye (exophthalmos) is often associated with a space-occupying orbital lesion or, less often, a congenitally shallow, underdeveloped orbit. Posterior malposition of the globe (enophthalmos) may result from active globe retraction caused by pain or from loss of supporting retrobulbar soft tissues. Congenital strabismus is a developmental abnormality that results in ocular asymmetry and is typically seen in Jersey, Shorthorn, and Holstein cattle.[7]

Unequal globe size can also account for ocular asymmetry. A congenitally small globe (microphthalmia) occurs as a genetic defect in cattle and horses.[7,8] Microphthalmia is frequently accompanied by multiple ocular anomalies and sometimes is associated with multiple organ involvement. Acquired variations in ocular size usually result from fibrosis and shrinking (phthisis bulbi) secondary to chronic uveitis, or stretching of the globe (megaloglobus, buphthalmos) because of glaucoma.

Asymmetry of the upper or lower lid may occur as a result of entropion, ectropion, blepharitis, conjunctivitis, or facial nerve paralysis (ptosis). Nictitating membrane (third eyelid) protrusion is frequently seen secondary to active retraction of the globe in response to ocular pain, enophthalmos caused by loss of orbital contents (as seen with marked dehydration or malnutrition), presence of third eyelid masses, orbital space-occupying masses, or neurologic disorders (e.g., Horner's syndrome, tetanus). Pupillary asymmetry, or anisocoria, may occur for a variety of reasons, including Horner's syndrome, intraocular diseases (uveitis, glaucoma, unilateral retinal lesions), diseases involving the optic nerve or brainstem, and previous use of pharmacologic agents such as atropine that alter iris smooth muscle function.

Table 39-1 Causes of Important Ocular Signs in Large Animals

Signs/Findings	Cause(s)		
	All Species (Ruminants and Horses)	Ruminants	Horses

1266

1267

The presence of an ocular mass may be the primary cause of ocular asymmetry. Ocular surface neoplasms are relatively common in horses and cattle. Ocular squamous cell carcinomas usually arise from nonpigmented tissues of the nictitating membrane, the lateral limbal region, or the eyelid margin. They may appear as irregularly raised surface masses or, less often, as smooth, vascularized lesions that invade the globe. Ulceration, exudation, and mucopurulent ocular discharge are frequent concurrent findings (see Ocular Neoplasia). Periocular sarcoids are also common in horses and appear as firm, raised, nonulcerative lesions.[9] Other ocular tumors, such as adenomas, adenocarcinomas, angiomas, angiosarcomas, mastocytomas, and melanomas, occur in large domestic animals but are relatively uncommon. Dermoids and orbital cysts are congenital masses involving the eye or orbit. Other nonneoplastic ocular masses seen in large animals include firm parasitic and foreign body granulomas and soft, fluctuant subconjunctival swelling characteristic of prolapsed periorbital fat. Ocular and orbital pseudotumors have also been described in the horse.[10]

39.7 OCULAR COLOR CHANGE

Changes in the color of the ocular or periocular tissues or the presence of opacities in the clear ocular media (cornea, aqueous humor, lens, or vitreous) are important features of ocular disease. Such changes must be differentiated from normal congenital differences in ocular pigmentation. Developmental color dilution or absence of ocular pigmentation results in light or multicolored irides (heterochromia iridis). When this occurs unilaterally, the resulting appearance may be striking. Examples of abnormal coloration include hyperemia of conjunctival (superficial) or episcleral (deep) blood vessels associated with ocular inflammation (see Red Eyes, Table 39-1), hemorrhage secondary to trauma or coagulopathies, pallor of the conjunctiva, which reflects severe anemia, and yellowing of the sclera and sometimes iris, indicating icterus.

Opacities of the ocular media may occur either as surface (corneal) or intraocular (anterior chamber, lens, or vitreous) phenomena. Sources of corneal opacification include melanosis ("pigmentation") secondary to chronic exposure, grayish scars from previous episodes of ulcerative keratitis, neovascularization secondary to chronic inflammation, and bluish discoloration caused by corneal edema. These color changes frequently occur in various combinations in more severe keratitis, especially those of infectious origin such as chronic keratoconjunctivitis caused by *Chlamydia* species, *Mycoplasma* species, or *Moraxella bovis*. Cataracts are perhaps the most obvious cause of intraocular opacities in large animals. However, the presence of exudates within the aqueous humor or vitreous, congenital vascular remnants in the vitreous, or retinal detachment may also account for intraocular opacities (see Table 39-1).

39.8 OCULAR DISCHARGE

Ocular discharges are characterized as serous ("epiphora"), mucoid (catarrhal), purulent, or hemorrhagic (sanguineous). The type of discharge may be used to aid in determination of the severity and chronicity of the eye disease. For example, serous discharge generally indicates milder forms of eye disease, whereas mucopurulent or hemorrhagic discharge indicates more serious disorders. A notable exception to this generalization is *equine recurrent uveitis* (ERU), which is a serious and potentially blinding disease but is usually associated with serous discharge (see Immune-Mediated Ocular Diseases). The nature of ocular discharge tends to change as the disease progresses or improves. This is most notable in inflammatory or infectious ocular diseases. Initially, the discharge is predominantly serous; however, it tends to become mucopurulent with chronicity (see Table 39-1).

Epiphora describes facial wetting and results from overflow of tears over the eyelid margin. This may result from excessive secretion of tears or from obstruction of the nasolacrimal system. In large animals, reflex lacrimation with an associated overabundance of tears is the typical response to ocular inflammation (e.g., conjunctivitis, keratitis, uveitis). When epiphora is noted, careful digital and visual examination for foreign bodies within the conjunctival fornix or under the third eyelid is indicated. Epiphora is generally one of the earliest signs of conjunctivitis, ulcerative keratitis, or anterior uveitis. In cattle with keratoconjunctivitis caused by *Moraxella bovis,* epiphora is present several days before visible corneal ulceration occurs[11] (see Infectious Bovine Keratoconjunctivitis).

Developmental defects or malformations of the nasolacrimal duct system (e.g., imperforate puncta) may account for ineffectual outflow of tears in neonates. In these cases the presence of epiphora may be misinterpreted as an overproduction of tears. Previously undiagnosed congenital defects may also be the cause of persistent ocular discharge in adult animals. Acquired obstructions of the nasolacrimal ducts may result from infections, foreign bodies, facial trauma, nasal tumors, or sinusitis that involve the duct system. When nasolacrimal obstruction is present, the nature of the ocular discharge depends on the chronicity of the lesion and the presence or absence of

infection within the nasolacrimal system. Whether congenital or acquired, simple nonseptic obstructions are characterized by epiphora. Occlusions with concurrent sepsis result in mucopurulent discharge from the eye or nostril on the affected side. Excessive mucus production is a feature of follicular conjunctivitis, possibly as a result of the rubbing of elevated lymphoid follicles on apposing conjunctival surfaces. Lymphoid follicles are noted in subacute or chronic forms of chlamydial conjunctivitis in sheep and with *Onchocerca* larval migration in horses. Mucoid ocular discharge may be observed concurrently with epiphora in acute ocular surface infections caused by viral or chlamydial agents. Excessive, tenacious mucus may also result from inadequate secretion of the aqueous component of tears (i.e., keratoconjunctivitis sicca). Although keratoconjunctivitis sicca is not diagnosed as commonly in large animals as it is in dogs, it has been reported in horses, usually as a complication of guttural pouch pathology.[12]

Purulent to mucopurulent material is the characteristic ocular discharge when bacterial organisms, including *Mycoplasma* species, are the primary cause of, or secondary contaminants in, ocular disease. Bacterial conjunctivitis occurs frequently in large domestic species and manifests as red eyes with copious amounts of mucopurulent ocular exudate. Ocular foreign bodies and surface masses (e.g., squamous cell tumors) typically have associated bacterial infections. Mucopurulent discharge in the absence of ocular inflammation suggests infection of the nasolacrimal sac (dacryocystitis) or ducts, with reflux of exudate from the lacrimal puncta.

Sanguineous of hemorrhagic discharge most often occurs after blunt or penetrating trauma to the eye (see Ocular Trauma). Foreign body penetration may damage the eyelid, conjunctiva, or globe, resulting in bleeding onto the ocular surface. Corneal ulcers may rupture and result in uveal prolapse and subsequent hemorrhage on the ocular surface. Ulcerative conjunctivitis from abrasion or infection may result in bleeding into the tear fluids. Similarly, ocular surface tumors may become ulcerative and cause bloody ocular discharge. Whenever blood is noted on the surface of the eye, it is imperative that a thorough ophthalmic examination be performed to determine the cause and to evaluate integrity of the globe.

1267

1268

39.9 OCULAR PAIN

Blepharospasm, epiphora, apparent photophobia, and periocular hyperesthesia are signs of ocular pain. Animals with severe ocular pain usually resist manipulation of the eyelids or any form of ocular examination by persistently jerking the head away from the examiner and by closing the eyelids tightly. In cases of persistent ocular inflammation, discomfort and pruritus may be manifested by rubbing and self-trauma to ocular or periocular structures.

Ocular pain may result from blunt or penetrating trauma. Corneal ulceration and uveitis are painful sequelae to ocular trauma. Limbal (scleral) ruptures from blunt injury or penetrating lacerations of the fibrous tunic may result in uveal prolapse (staphyloma), which is extremely painful. Periocular trauma may cause eyelid swelling or paresis with exposure and drying of ocular surface tissues, resulting in painful ulcerative keratitis. Inflammatory diseases of nontraumatic origin (e.g., infectious keratoconjunctivitis, ERU) may also cause severe ocular pain in an affected animal. Other causes of ocular pain include frictional irritation, resulting from entropion, trichiasis, distichia, or ectopic cilia, or direct irritation of the ocular surface by foreign material. Foreign bodies causing ocular irritation in large animals are typically plant materials such as seeds, hay stems, straw, twigs, bark, or thorns, although particles of sand or soil can also cause severe ocular irritation. Nonembedded particulate matter is usually entrapped by mucus and washed out of the eye by reflex tearing; therefore it typically results only in transient discomfort. By contrast, embedded foreign material (i.e., between ocular surface layers or within ocular tissues) causes persistent ocular pain.

39.10 BLINDNESS

Visual deficits in large animals manifest in a variety of ways. Obvious signs include bumping into objects in the path of locomotion and being unable to respond to visual stimuli such as light or hand motions. Other signs of blindness are reliance on stationary objects, such as fences, railings, or other animals, to maneuver within the environment. Behavioral changes include reluctance to move or to venture into unfamiliar areas. The nonvisual animal is frequently found standing isolated from the group. Searching nystagmus is also seen in some animals with congenital blindness.

Nonvisual animals attempt to compensate for loss of vision with their other senses, resulting in behaviors that seem peculiar. For example, as an apparent overcompensation for visual deficits, the blind animal may raise its head extremely high with the ears erect at the slightest auditory stimuli. A similarly dramatic response to olfactory stimuli may be noted in affected animals when snorting or intensive sniffing associated with nervousness and maximum neck extension is observed. Frequently, blind animals will show exaggerated elevation of the limbs while walking. This must be differentiated from true hypermetria (see Chapter 8). Partial loss of vision may be difficult to determine, and detection depends on observing more subtle behavioral changes such as slight head cocking or tilting, difficulty maneuvering in dim light, or shying and startling from objects on one side or objects present in some specific part of the visual field. Animals may effectively compensate for congenital blindness or slow diminution of vision, particularly when they remain with other unaffected animals in a familiar environment. Visual disturbance may not be apparent until an affected animal is isolated or moved to an unfamiliar area.

* See Cloudy Eye (Ocular Opacities) in Table 39-1.

There are numerous causes of blindness in large animals, including those that involve only the visual system and some that involve other nervous system tissues or are multisystemic (Box 39-1). A functional approach to blindness involves anatomically classifying the cause as one of the following:

- Obstruction of the ocular media (light does not reach the retina).
- Failure of the retina to process the light appropriately.
- Failure of the central nervous system (CNS), including the optic nerve, to transmit or assimilate the visual stimuli appropriately.

1268

1269

Assessment of the pupillary light reflexes (PLRs) aids in the localization of the lesion. Animals with lesions involving the retina, optic nerves, optic chiasm, or optic tracts generally do not have a normal PLR, whereas those with more central ("higher") lesions involving the lateral geniculate bodies, optic radiations, or occipital (visual) cortex are likely to exhibit a normal PLR (see Chapter 8).

39.11 OCULAR TRAUMA

R. DAVID WHITLEY

KRISTINA R. VYGANTAS

ELIZABETH M. WHITLEY

39.12 CAUSES OF TRAUMA

Because the eye is anatomically prominent in horses and food animals, it is prone to blunt and sharp trauma, which can range in severity from a mild abrasion caused by a conjunctival foreign body to a severe corneal laceration with globe rupture and orbital bone fracture. Ocular injuries may result from a variety of causes, including foreign materials such as soil, sand, or stones, which may be thrown into the eye during running or by the wind; trauma from disciplinary action; scratches by vegetable matter such as hay, weed stems, tree limbs, or thorns; exposure to chemical irritants; and sudden, violent head movements during training, working, or

grooming. Other sources of ocular injury include stanchion, stall or trailer latches, hooks, protruding nails, bucket handles, fencing materials, and other animals, particularly horned ruminants.

Recumbent neonates and animals with CNS disease or severe illnesses that cause depressed mentation often suffer eye injuries from abrasion by debris or bedding materials such as sand, straw, hay, or wood shavings. Such injuries may be prevented by protecting the eye from trauma through the use of a padded hood or soft mats under the head, by keeping the cornea well lubricated in dehydrated animals with reduced blinking frequency, and by administering sedation to prevent thrashing. Following ocular trauma, opportunistic or pathogenic organisms may become established in the wound bed and may cause superficial or deep corneal infections.[13] Ocular flora native to the conjunctiva include potential pathogens that may cause severe infections.[14]

39.13 OCULAR EXAMINATION IN CASES OF HEAD TRAUMA

The goals of examination are to determine the degree of ocular trauma and to offer a prognosis for recovery of vision and preservation of the eye. The history should elicit information as to the cause and duration of the injury, previous ocular and systemic disease or therapy, and a description of any recent sedation, anesthesia, or therapy.

Blunt or sharp facial trauma frequently results in damage to the orbit and globe, including fractures or soft tissue injuries of the orbit, corneal abrasions and edema, hyphema, traumatic uveitis, lens luxation, traumatic cataract, vitreal hemorrhage, retinal tear or detachment, corneal or scleral rupture, or proptosis. Therefore, the orbit and globe and vision should be examined as thoroughly as possible when evaluating a patient with facial trauma.

Ophthalmic examination can be performed only after adequate restraint of the head (see previous discussion). Intravenous (IV) sedation, sensory and motor nerve blocks, topical anesthesia, and the use of a halter, twitch (in horses), or nose tongs (in cattle) often are necessary for adequate examination of the traumatized eye.

39.14 TRAUMA TO THE ORBIT

Orbital injuries in domestic animals frequently include fractures of the orbital rim and zygomatic arch and damage to the supraorbital process of the frontal bone.[15] Fractures of the orbit may be identified by palpation, conventional or digital radiography, computed tomography (CT), or magnetic resonance imaging (MRI). Contusions or lacerations of orbital soft tissues and temporary or permanent neurologic dysfunction also may be present.

Radiographic examination of the bony orbit in large animals is technically difficult and often unrewarding with conventional radiography. Standard lateral and dorsoventral views require powerful radiographic equipment for penetration of bony structures in horses and cattle.[16] Large fractures may be identified, but distinct delineation of the bony orbit is difficult because of overlying sinus and nasal structures. An oblique view of the frontal bone is often the most helpful projection.[16] This view may be taken with a portable machine because only minimal radiographic penetration of skull structures is required. Outlining the orbit and surrounding bony structures allows identification of fractures, osteomyelitis, with or without bony sequestra, and soft tissue abnormalities, including swelling and radiopaque foreign bodies. If a periorbital sinus is involved in the fracture, subcutaneous emphysema may be present. The use of digital radiology may allow enhanced visualization of the bony structures of the orbit, especially when only subtle changes are present.[17] Digital radiography systems used in conjunction with portable equipment may provide adequate detail in standard as well as oblique projections. CT and MRI are available at many referral centers. Detail of the bony and soft tissue structures is greatly enhanced by the cross-sectional views acquired by CT, as are the structures of the calvarium, sinuses, and teeth.[17] MRI is also very beneficial in

delineating soft tissue abnormalities within the orbit and sinuses.[17–19] Immediate evaluation for orbital fractures should include careful examination of the globe. In cases with substantial swelling, ice packs applied to the fracture site may reduce swelling. Systemic antiinflammatory therapy (e.g., flunixin meglumine, ketoprofen, phenylbutazone) may also be given. Systemic antibiotics should be used if sinus involvement is suspected. If the fracture fragments are only minimally displaced, surgical intervention may not be required. Surgical repair should be considered if fragment displacement or entrapment of extraocular muscles has occurred or could occur.[16,20] Trauma sufficient to cause fractures may also result in neurologic dysfunction and immobility of the eyelids.

If eyelid movement is impaired, the globe must be adequately protected and lubricated until neurologic function returns. If the globe is only minimally exposed, a sterile ophthalmic lubricant may be used at least three or four times daily. In more severe cases, a nictitating membrane flap or temporary partial tarsorrhaphy may be required. If neurologic dysfunction is permanent and results in significant exposure conjunctivitis or keratitis, partial or complete permanent tarsorrhaphy should be performed.[16] Enucleation or enucleation with the placement of an orbital prosthesis may be required for severely affected eyes.

Scleral rupture is another potential consequence of blunt trauma to the orbit and globe. A recent study found that the most consistent clinical sign of scleral rupture in horses is eyelid and conjunctival swelling.[21] Other clinical features of this condition are hyphema, subconjunctival hemorrhage, and a collapsed anterior chamber. 1269
Ultrasonographic findings include poorly defined scleral margins and echoic/hyperechoic material in the anterior 1270
and posterior chambers and in the vitreous.[21]

Traumatic puncture wounds of the eyelids and conjunctiva may result in orbital cellulitis and exophthalmos in food animals and horses. The onset of swelling may be sudden. Pyrexia and leukocytosis may be present. If a retrobulbar abscess occurs, temporomandibular movement causes extreme pain; the animal may have the eyes partially closed, be off feed, and stand with the neck extended. The client may observe a relatively sudden onset of exophthalmos, eyelid swelling, severe chemosis, and exposure keratitis.[16,22] Therapy should consist of systemic and topical antibiotics. Ophthalmic ointments and lubricants should be used to provide protection from desiccation of the exposed cornea and conjunctiva. With time, the cellulitis may organize into a discrete abscess that can be located by palpation or ultrasound. The wound or abscess should be debrided or drained to facilitate healing, especially if a well-organized abscess is present.

Although traumatic proptosis is uncommon, it may occur in horses and food animals. The prognosis for return of vision is guarded to poor, depending on the extent of the damage to the optic nerve and retina. If the globe is ruptured or the extraocular muscles are avulsed, the eye should be enucleated. If the extent of the damage cannot be evaluated initially, the globe should be repositioned, a temporary tarsorrhaphy performed, and the globe reevaluated after 7 to 10 days of topical therapy. Treatment should include topical broad-spectrum antibiotics and atropine. With severe fractures or serious ocular damage, consultation or referral to the appropriate specialist is advised.

39.15 TRAUMA TO THE EYELID

Eyelid trauma is frequently accompanied by injuries to other ocular structures. Careful ocular examination should be part of the evaluation of animals with eyelid trauma.[23] Injuries may range from swelling (blepharedema) or orbital cellulitis to extensive lacerations and avulsion. Blepharedema may be accompanied by hemorrhage and usually resolves quickly without therapy; however, recovery may be hastened by the use of ice packs and systemically administered ketoprofen or flunixin meglumine.

Horses are particularly prone to eyelid lacerations because of the prominence of the eye and their tendency toward sudden head movements when startled. Lacerations may be divided into those without eyelid margin involvement, those with eyelid margin involvement, and avulsions of part or all of an eyelid. For all types of eyelid injury, several basic principles should be followed. Lacerations should be treated promptly to avoid distortion from excessive swelling, infection, scarring, and loss of function. Lacerated or displaced tissue should not be excised. It is impossible to replace the mucocutaneous junction of the eyelid margin. If eyelid margin is sacrificed, the risk of scar formation and secondary corneal damage is high. The laceration should be thoroughly and carefully flushed with sterile saline and explored to remove all foreign material. In acute trauma, cold compresses may assist in decreasing swelling. In suturing an eyelid laceration, it is essential to preserve the eyelid margin; therefore, eyelid lacerations should be repaired with minimal debridement. In cases of long-standing or infected lacerations, the wound should be packed with an antibiotic dressing for 24 to 48 hours before surgical repair.[24] In cases of avulsion of part or all of the eyelid, a variety of blepharoplastic procedures may be performed to help restore functional eyelid margin.[23–25]

For a more detailed description of the principles of surgical repair of the eyelids, an ophthalmic surgical text is recommended.[23,24,26]

Postoperative care of all eyelid lacerations should include standard wound hygiene, application of fly repellent and topical ophthalmic antibiotics, and prevention of self-trauma. In contaminated wounds, systemic antibiotic therapy is indicated for 5 to 7 days. Tetanus prophylaxis should be administered.

Improper repair of eyelid lacerations can lead to abnormal function and secondary problems, including chronic epiphora and associated dermatitis, exposure keratitis, ulcerative keratitis, cicatricial entropion or ectropion, conjunctivitis, and pigmentary keratitis.

39.16 TRAUMA TO THE NICTITATING MEMBRANE

Lacerations involving the nictitating membrane (third eyelid) should be repaired to avoid irritation and damage to the cornea. This appears to be more important in horses than in ruminants. The margin should be realigned as precisely as possible, and the lacerated conjunctiva should be repaired with absorbable, small suture material such as 5-0 to 7-0 polyglactin.* Topical ophthalmic antibiotics should be used three to six times daily for 7 to 10 days. The entire nictitating membrane should be excised only if it is irreparably damaged.

* Vicryl, Ethicon, Somerville, NJ.

39.17 TRAUMA TO THE CONJUNCTIVA

Conjunctival lacerations result in swelling (chemosis) and hemorrhage. The cornea and sclera should be examined carefully for evidence of lacerations or perforation. If the globe is excessively soft on digital palpation, the anterior chamber is shallow or flat, or hyphema or subconjunctival hemorrhage is present, a concurrent scleral laceration is probable.[12,21]

Chemosis and hemorrhage frequently resolve without therapy. However, if the chemosis is severe enough to cause exposure and drying of tissues, topical sterile ophthalmic lubricants or antibiotic ointments are indicated to prevent secondary irritation. Conjunctival lacerations rarely require closure unless they are extensive. Subconjunctival hemorrhage sustained during parturition is common in foals and calves and requires no therapy, although topical ocular lubricants or antibiotic ointments are often prescribed.

39.18 TRAUMA TO THE CORNEA

Corneal injuries in horses and food animals include blunt compressive trauma, foreign body penetration, ulcerative keratitis, and lacerations. Corneal perforation often results in iris, or iris and ciliary body, prolapse. Therapy is dictated by the type and extent of corneal injury, the complications encountered, the intended use and economic value of the animal, and other financial considerations.

39.18.1 Blunt Trauma to the Cornea

Blunt trauma to the globe from lead shanks, whips, and other objects can result in corneal endothelial injury and subsequent edema. Signs of traumatic uveitis also may accompany such an injury. The corneal edema that results from blunt trauma to the globe may be focal, linear, or diffuse. Therapy for blunt trauma includes a topical hypertonic (5%) saline solution or ointment two to four times a day to decrease corneal edema.[27] A linear keratopathy, characterized by a nonedematous, deep, striate, refractile opacity in the cornea, may represent a focal thinning or break in Descemet's membrane that has resulted from blunt trauma to the cornea. This type of lesion must be distinguished from Haab's striae, which are linear breaks in Descemet's membrane that result from elevated IOP in glaucoma.

1270 1271

39.18.2 Corneal Foreign Bodies

Plant matter embedded in the epithelium or superficial stroma is the most frequently encountered corneal foreign body. Foreign bodies usually are easily removed with a moistened, cotton-tipped applicator or ophthalmic forceps. Sedation, motor or sensory nerve blocks, and topical anesthesia facilitate removal. Culture and sensitivity tests and cytologic examination of corneal samples are recommended before therapy is initiated. The cornea is stained with fluorescein dye to evaluate the extent of corneal ulceration. While awaiting laboratory results, medical therapy should include a topical ophthalmic antibiotic (bacitracin-neomycin-polymyxin, gentamicin, or tobramycin three or six times daily) and atropine (as needed). The prognosis is guarded until the cornea heals; the eye should be reevaluated in 24 to 48 hours.

Complications of corneal foreign bodies include bacterial and fungal infection, corneal perforation, and severe corneal scars that may restrict vision. Subpalpebral lavage systems are used in severe injuries when frequent, prolonged therapy is needed or when treating intractable animals (see later under Bacterial Keratitis in Horses).[28]

39.18.3 Corneal Ulcers

Corneal ulcers in horses are usually initiated by trauma and should be considered contaminated by bacteria or fungi until proved otherwise. Trauma may play a lesser role in food animals in which primary infectious etiologies are more common (see Infectious Bovine Keratoconjunctivitis). The conjunctival fornices and eyelids should be carefully examined for foreign material. Diagnosis is based on cytologic examination, culture and sensitivity testing of corneal samples, and fluorescein staining of the cornea. Material for bacterial and fungal culture is collected from the ulcer with sterile rayon-tipped swabs. Cotton swabs are less satisfactory because cotton exhibits some antimicrobial properties. The eyelid margins and skin should be avoided, and better culture results are obtained if the swab is moistened with a sterile solution (sterile water or saline) before specimen collection. The most reliable results are obtained if the swabs are placed in a transport medium at the

time of collection.* The use of a culture tube with saline in an enclosed, breakable ampule is also helpful.[29] The ampule is crushed, and fluid is allowed to moisten the swab before specimen collection. Immediately after collection, the swab is replaced in the tube or inoculated onto standard bacterial and fungal agar plates, or blood agar and thioglycolate broth.

Corneal scrapings for microscopic examination are collected with the use of topical anesthesia. The eyelids are retracted, and the margin of the corneal ulcer is gently rubbed with a small brush, cytology spatula, or the blunt, handle end of a Bard-Parker scalpel blade until a small amount of cellular material is collected. This material is transferred to two to six clean glass slides, spread over a 1-cm (0.4-inch) area and allowed to air-dry. One smear is stained with Diff-Quik; one with Wright-Giemsa, periodic acid—Schiff (PAS), or GMS for fungal hyphae; one with Gram stain; and possibly one with new methylene blue.

Therapy of corneal ulcers is based on the removal of the cause if it is still present, control or prevention of infection with topical antimicrobials, use of topical atropine for relief of painful ciliary body spasm and prevention of synechia, and, in horses, the systemic use of nonsteroidal antiinflammatory drugs (NSAIDs) such as flunixin meglumine, ketoprofen, or phenylbutazone. Some ophthalmologists also like to sterilize the base of the ulcer by application of povidone-iodine solution (Betadine) diluted 50:50 with sterile saline or collyrium. The initial choice of topical antibiotic should be based on the results of cytologic evaluation and later modified, if necessary, according to the results of culture and sensitivity testing. One study showed that oxytetracycline combined with polymyxin B had in vitro efficacy against isolates from infectious keratitis that was comparable to gentamicin and superior to chloramphenicol.[30] If cytology demonstrates fungal hyphae, initial therapy with a topical antifungal agent should be instituted immediately. One study demonstrated that natamycin,* miconazole, itraconazole, and ketoconazole are superior to fluconazole† based on the results of in vitro susceptibility testing.[31] Voriconazole is a newer antifungal drug that may be compounded for use in veterinary ophthalmology. Subpalpebral lavage systems greatly facilitate the delivery of topical medication to the equine eye (see Bovine Keratitis in Horses).[28,32]

Surgical intervention should be considered in cases of deep corneal ulceration and especially when Descemet's membrane is exposed. Surgical procedures most often used for corneal ulceration include conjunctival pedicle flap, keratoplasty, and tarsorrhaphy.[12,33–35] Ophthalmic tissue adhesives and soft contact lenses may also be used as nonsurgical therapy for deep corneal ulcers. Perforating ulcers with iris prolapse and mixed bacterial and fungal keratitis or ulcers present greater than 2 weeks usually have a poor visual outcome.[36]

39.18.4 Corneal Lacerations

Corneal lacerations may be caused by sharp, protruding objects or projectiles. Corneal lacerations can occur with or without scleral laceration and, if they are nonperforating, may be treated as corneal ulcers. By contrast, perforating corneal lacerations must be repaired surgically. Preoperative preparation includes tetanus prophylaxis (horses and goats), systemic antibiotics, and sample collection for corneal culture and sensitivity. Ocular ultrasonography is very useful in determining the integrity of intraocular structures. However, care must be exercised during ocular examination, ultrasonography, and during surgery and anesthesia (especially induction and recovery) because extrusion of the intraocular contents may occur if excessive pressure is exerted

on the globe or if the eyelids are forced open. In some cases, complete examination of the globe should be delayed until the animal is anesthetized.

General anesthesia, adequate magnification, proper instrumentation, appropriate suture material and needles, and adequate postoperative care are necessary for successful repair of a corneal laceration. Postoperative therapy must include topical antibiotics and mydriatics/cycloplegics, along with systemic antiinflammatory agents.[34,37] The prognosis for recovery of vision and preservation of the globe generally is guarded. Complications that may occur after repair of corneal lacerations include phthisis bulbi, corneal fibrosis, synechia formation, blindness, retinal detachment, cataract formation, uveitis, endophthalmitis, bacterial or mycotic keratitis, and wound dehiscence with subsequent iris prolapse.

1271

1272

The prognosis after surgical repair of corneal or corneoscleral lacerations is best when the animal is presented immediately with a small wound in which the cornea or sclera is sealed and the anterior chamber has re-formed. Minimal hyphema, clear intraocular media, a clearly visible fundus, and laceration length of less than 15 mm are additional findings that indicate a favorable prognosis.[33,36] In horses the success rate when only the cornea is involved is about 70% for recovery of vision and 90% for a cosmetically acceptable globe.[33] With corneoscleral lacerations the prognosis is much worse. In our experience the success rate in such cases is 20% for recovery of vision and 70% for a cosmetically acceptable globe. Most phthisical globes are not considered cosmetically acceptable. Therefore, enucleation should be considered initially with severe corneoscleral lacerations because the prognosis is poor for return of vision and guarded for preservation of the globe. Several surgical procedures have been described in horses to provide a cosmetic appearance to the globe and orbit, including placement of an intraocular silicone prosthesis.[38–40]

39.19 TRAUMA TO THE UVEAL TRACT

Trauma to the globe can damage the iris, ciliary body, and choroid. The resulting inflammatory response may range from very mild with rapid recovery to loss of vision and chronic discomfort. Signs of inflammation of the iris and ciliary body include blepharospasm, epiphora, miosis, aqueous flare, corneal edema, fibrin in the anterior chamber, hyphema, hypopyon, low IOP, and synechia formation. Concurrent damage to the corneal epithelium may be present and must be evaluated with fluorescein dye. Damage to the choroid may also affect the retina and lead to retinal detachment or degeneration.

Traumatic uveitis is treated in a manner similar to uveitis of other etiologies. Therapy is directed toward dilating the pupil to prevent synechia formation, cycloplegia to prevent painful ciliary spasm, and controlling the intraocular inflammatory response. Topical atropine is instilled to maintain mydriasis and provide cycloplegia. Topical corticosteroids and prostaglandin inhibitors such as 0.1% diclofenac* are used to decrease inflammation of the anterior segment.

The topical corticosteroid of choice is 1% prednisolone acetate or 0.1% dexamethasone.[16,41,42] Subconjunctival injection of corticosteroids may also be quite beneficial in controlling inflammation. However, the use of topical and subconjunctival corticosteroids must be avoided in the presence of corneal ulceration or abrasion. Systemic medication should include flunixin meglumine, ketoprofen, phenylbutazone, or oral corticosteroids. In horses, prednisolone is given by mouth at 0.5 to 2 mg/kg for 7 to 21 days. Care must be taken to avoid secondary complications from systemic corticosteroids.

Trauma-induced hyphema usually has a good prognosis if the blood has clotted and fills less than half the anterior chamber. Stall rest, topical 1% atropine, topical corticosteroids, and systemic antiinflammatory therapy should be

instituted to control the associated uveitis. If a penetrating wound is suspected, topical and systemic antibiotic therapy should be included with periodic fluorescein staining. Surgical intervention to remove large blood clots is rarely indicated because it may result in additional bleeding or may worsen the uveitis. Dilute tissue plasminogen activator* (tPA, 25 to 50 µg) may be injected into the anterior chamber to disrupt or lyse intraocular hemorrhage and fibrin and to aid in resolution of synechiae. For maximum effectiveness, tPA should be used within 24 to 72 hours of clot formation.[43,44] Systemic tPA for use in humans is diluted for intraocular use but is expensive. However, diluting the drug and repackaging it into sterile vials that are stored at −70° C and then thawed for injection has made the cost more reasonable for veterinary use.

Chronic uveitis after ocular trauma may be associated with lens damage or the introduction of infectious or foreign agents into the eye and carries a poor prognosis. If the lens is ruptured, its surgical removal is advocated. Ocular perforation is a frequent cause of panophthalmitis in food animals and horses. Although therapy consists of systemic and topical antibiotics, as well as tetanus prophylaxis in susceptible species, panophthalmitis usually necessitates eventual enucleation.

* Voltaren, Novartis, East Hanover, NJ.

* Activase, Genentech, South San Francisco, CA.

39.20 TRAUMA TO THE LENS

Blunt or sharp trauma to the eye may damage the lens by causing lens opacity (cataract), rupturing the lens capsule, or less often may cause a shift in position (subluxation or luxation). A luxated lens should be removed if it causes obstructive glaucoma or chronic corneal edema from endothelial contact, or if it becomes cataractous and reduces vision.

Release of lens protein into the eye after lens capsule rupture may induce severe granulomatous uveitis. In such cases the eye should be treated vigorously for lens-induced uveitis with topical atropine and topical and systemic antiinflammatory drugs. If the globe has been penetrated, topical and systemic antibiotics are indicated. The prognosis for preservation of vision is poor. Lens removal is often required to control the inflammatory response.

Cataracts (lens opacities) associated with ocular trauma may occur acutely or develop weeks after the initial injury. The opacity may be only focal and not appreciably affect vision, or it may be complete and cause a visual deficit. If the remainder of the eye is normal, surgical removal of the cataractous lens may improve vision.[45] Removal of cataracts secondary to uveitis is not recommended currently; however, with the advent of new surgical techniques, procedures such as combined vitrectomy (possibly to remove the immunologic stimulus in recurrent uveitis) and lensectomy may become more commonplace.[46]

39.21 TRAUMA INVOLVING THE VITREOUS

Trauma to the eye may result in hemorrhage into the vitreous or release of inflammatory products that cause vitreal degeneration. Either circumstance can result in vitreal syneresis (liquefaction), formation of vitreal traction bands, and subsequent retinal detachment. Symptomatic treatment of inflammation is generally adequate; however, vitrectomy may be beneficial in the management of severe vitreal hemorrhage.[16] Foreign material that becomes entrapped in the vitreous may be an inciting factor for endophthalmitis. If infectious endophthalmitis is suspected, diagnostic paracentesis of the vitreous or anterior chamber should be performed to obtain samples for bacterial and fungal culture and for sensitivity and cytologic examination. After the samples are obtained, but before removing the needle from the globe, 200 µg gentamicin and 2.2 mg cefazolin, or 200 µg gentamicin and 1

mg vancomycin, should be injected into the vitreous.[47] Further therapy should be based on culture and sensitivity (C&S) results, as well as cytologic findings. If a foreign body is identified, removal and vitrectomy may be beneficial, but the prognosis for successful treatment is poor.

39.22 TRAUMA TO THE RETINA

Retinal tears, hemorrhage, edema, and detachment may be caused by trauma.[48,49] In cases of opaque ocular media, retinal separation may be diagnosed by ocular ultrasonography (Fig. 39-9). Retinal degeneration may follow ocular trauma. Retinal hemorrhage and edema should be treated with systemic corticosteroids. With current technology, surgical repair of retinal tears, lacerations, or detachments in food animals and horses may be feasible in selected cases.

39.23 TRAUMA TO THE OPTIC NERVE

The pathogenesis of damage to the optic nerve is not well understood. Shearing forces at the optic foramen from displacement of the brain after severe head trauma (Fig. 39-10), direct contusion or avulsion of the optic nerve, or loss of blood supply to the nerve and subarachnoid hemorrhage probably all have roles in optic nerve injury.[50] Early examination may reveal only a dilated pupil that may be partially or completely unresponsive to light. Later, changes may include optic nerve atrophy (Fig. 39-11) and peripapillary retinal pigmentation changes. Therapy with systemic antiinflammatory drugs may be of benefit, but severe damage is usually irreversible.

Traumatic optic nerve atrophy is usually characterized by sudden onset of unilateral or bilateral blindness; dilated, fixed pupils; and a lack of menace response. In horses the traumatic episode is frequently characterized by damage to the poll from rearing over backward and striking the back of the head, from rearing up and hitting a ceiling beam, or from blunt trauma (blows) to the side or front of the face. The animal usually stands without loss of consciousness, and the injury is not considered serious by the owner at the time. Initially, blindness with a normal-appearing ocular fundus is observed.

Fig. 39-9 Ocular ultrasound of a horse eye after blunt trauma to the globe. Note the characteristic V-shaped retinal detachment.

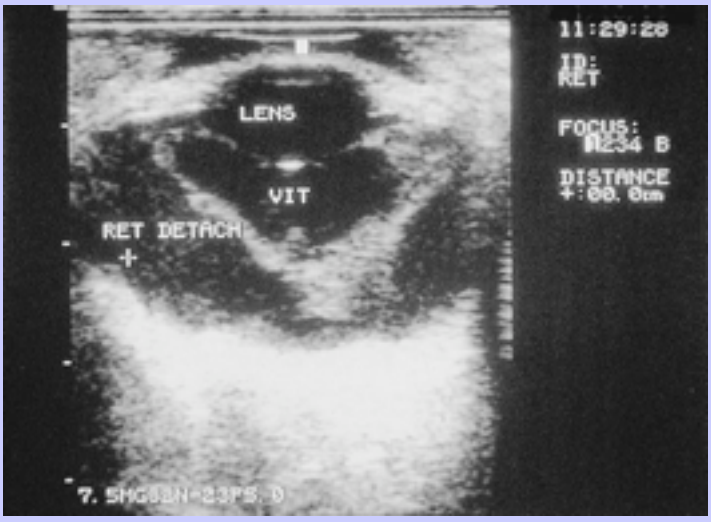

Fig. 39-10 Optic nerves and chiasm of a foal that was blind as a result of head trauma. Note the constrictions of the optic nerves caused by necrosis and degeneration. *Courtesy Dr. C.L. Martin.*

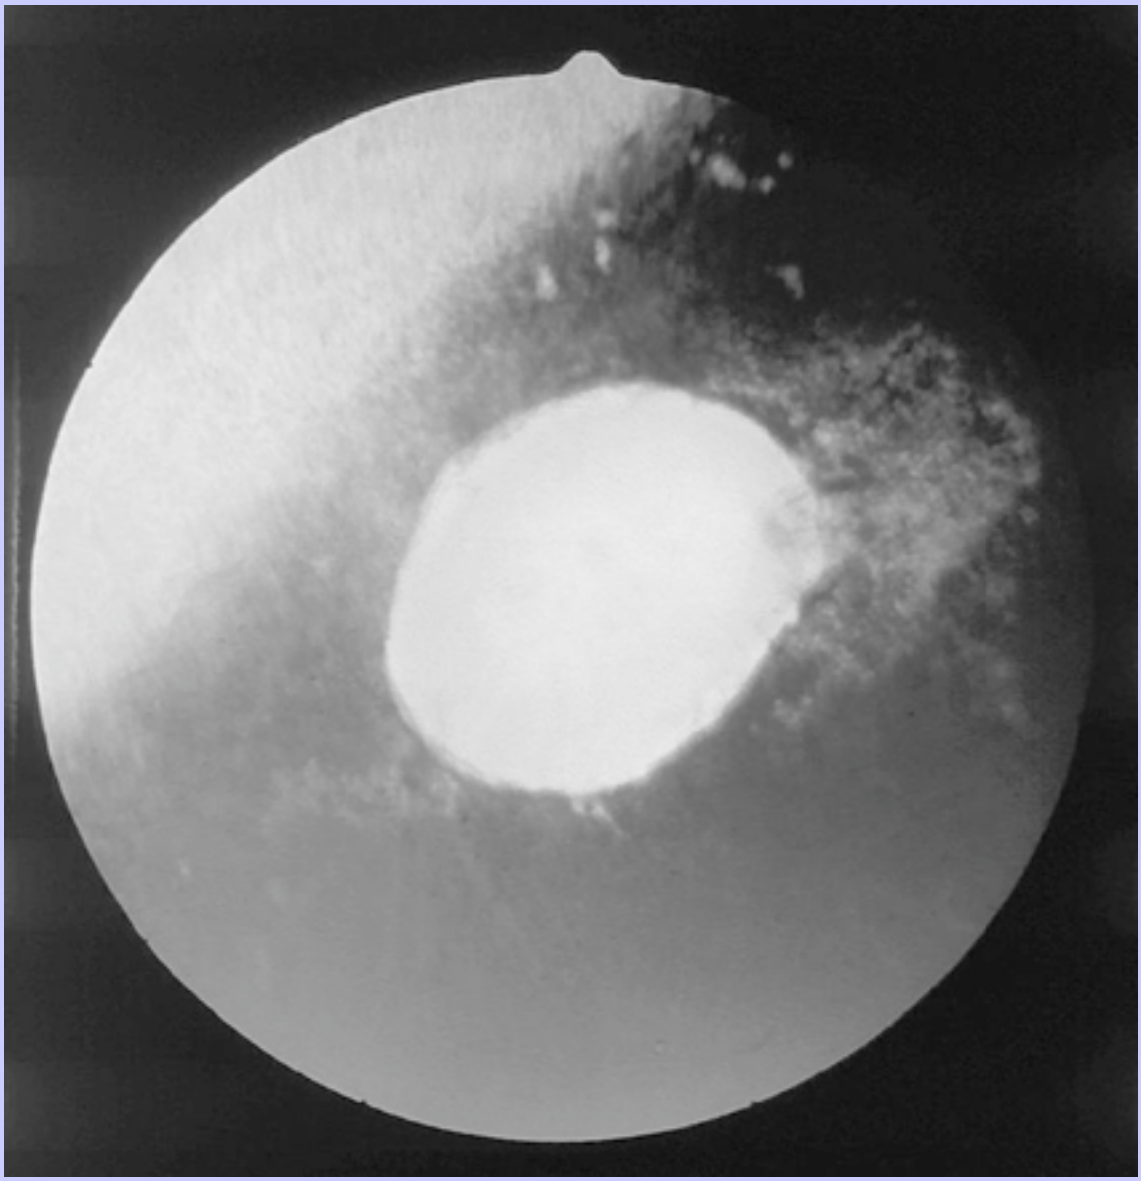
Fig. 39-11 Appearance of the optic nerve 3 months after head trauma in a horse. Note the pale optic disc and peripapillary retinal degeneration. *Courtesy Dr. C.L. Martin.*



Within 3 to 4 weeks after the trauma, examination of the fundus reveals a pale optic disc (see Fig. 39-11). Later, loss of peripapillary retinal vessels is usually evident. The optic disc often appears depressed, with increased prominence of the lamina cribrosa. Confirmation of optic nerve or optic tract lesions causing blindness may be made by the absence of a direct pupillary light reflex with a normal electroretinogram. In some cases the pathologic lesion is a rupture of the nerve axons from stretching forces produced by movement of the brain.[50] Chiasmal hemorrhage and fractures of the basisphenoid bone may be observed at necropsy. Therapy with

systemic corticosteroids (dexamethasone, 1 mg/kg) and IV dimethyl sulfoxide (DMSO) has generally not been successful,[50] although the lack of response to medical therapy appears related to the severity of the injury. 1273

1274

A segmental optic nerve atrophy involving one to three quadrants of the optic disc occurs in horses. The appearance is characterized by pallor, loss of normal vasculature, and increased prominence of the lamina cribrosa in the affected quadrants. The etiology is unknown; however, traumatic injury is suspected in most cases. Response to medical therapy is poor.

39.24 CHEMICAL INJURY

Ocular irritation caused by insecticides and disinfectants inadvertently applied to the eye is relatively common in the farm or ranch setting. Chemical burns to the cornea and adnexa may have serious consequences and may warrant a poor prognosis for salvage of the eye. Alkali burns are more severe than acid burns. Corneal burns from acids tend to be sharply demarcated and nonprogressive, whereas alkali burns cause progressive coagulation, melting, and sloughing of the corneal stroma.[16] Chemically induced melting of the cornea must be differentiated from bacterial and fungal infections. Treatment for a suspected or known chemical burn should include lavage of the affected area with copious amounts (500 to 2000 mL) of sterile saline solution. Tap water may be used by the owner until veterinary assistance is available. It may be necessary to sedate the animal. No attempt should be made to neutralize the substance because this may cause precipitation within the cornea. The damage should then be evaluated with the aid of local nerve blocks.

Treatment should include appropriate topical antimicrobials, atropine, and a collagenase inhibitor such as autologous serum or possibly acetylcysteine,* which inhibits collagenases and metalloproteinases by binding calcium. The commercially available preparations contain 10% and 20% acetylcysteine and should be diluted to 5% and 10% to avoid epithelial toxicity. Acetylcysteine lasts only about 4 days once opened and should be refrigerated. Hourly application of serum or acetylcysteine may be needed. Systemic antiinflammatory drugs should be used to control secondary uveitis. Therapeutic soft contact lenses have been used to protect the corneal stroma in patients with extensive corneal ulcerations.

* Roxane Laboratories, Columbus, OH.

39.25 THERMAL INJURY

Facial burns secondary to barn or stable fires may damage the eyelids, conjunctiva, and cornea. Thermal injuries also may cause anterior uveitis and exfoliation of the lens capsule. Therapy for minor burns to the eyelids is directed toward keeping the injured area moist with antibiotic dressings and protecting the cornea if eyelid dysfunction occurs. Treatment for injury to the conjunctiva or cornea should include topical antibiotic and systemic antiinflammatory drugs in horses. Full-thickness eyelid burns may require grafting procedures to protect the cornea and to minimize scarring.[24,26] Third eyelid or conjunctival flaps may be required to protect the cornea until eyelid function returns.

39.26 INFECTIOUS OCULAR DISEASES

JOAN DZIEZYC

NICHOLAS J. MILLICHAMP

This section describes the major infectious ophthalmic diseases of large animals (Table 39-2), concluding with a discussion of infectious bovine keratoconjunctivitis (IBK), or "pinkeye," the most common ocular disease of cattle.

39.27 MYCOPLASMAL KERATOCONJUNCTIVITIS IN GOATS AND SHEEP

39.27.1 Definition and Etiology

Mycoplasma conjunctivae has been frequently isolated throughout the world from epidemics of keratoconjunctivitis, respiratory disease, and arthritis in goats and sheep.[51–54] *Mycoplasma mycoides* subsp. *mycoides* has been isolated from an epidemic of mastitis, arthritis, and keratoconjunctivitis in goats.[55] *Acholeplasma oculusi (oculi)* has been isolated from sheep and goats in epidemics of keratoconjunctivitis.[56,57] *Mycoplasma agalactiae* and *Mycoplasma arginini* have also been described as causing keratoconjunctivitis and systemic disease.[58]

39.27.2 Clinical Signs and Differential Diagnoses

Clinical signs of mycoplasmal keratoconjunctivitis include epiphora, conjunctival hyperemia, and occasionally follicular conjunctivitis. In experimental conjunctival inoculation with *M. conjunctivae*, clinical signs began on day 2 and lasted for 5 weeks.[59] Later in the disease, keratitis with corneal neovascularization (Fig. 39-12) and occasionally anterior uveitis can be seen.[51,60] One case of choroiditis and hyalitis has been described.[61] Signs can be seen in individuals, as well as in herd or flock outbreaks. The disease is usually unilateral but can be bilateral. Differential diagnoses include other infectious causes of keratoconjunctivitis, such as *Chlamydia* species (sheep), *Branhamella (Neisseria)* species, aerobic bacteria, parasites, and infectious bovine rhinotracheitis (goats), as well as noninfectious causes such as trauma.

39.27.3 Clinical Pathology

In conjunctival scrapings taken early in the disease, many neutrophils are seen; later, lymphocytes predominate. Plasma cells and necrotic epithelial cells are also seen.[62] Organisms can be seen occasionally in epithelial cell cytoplasm as coccobacillary or varied forms.[61] Pigment granules can be mistaken for organisms.[56,62,63]

Mycoplasmal organisms can be cultured and identified from conjunctival swabs; serum antibody titers can be measured,[64,65] or polymerase chain reaction (PCR) can be used to identify *M. conjunctivae* in conjunctival smears.[66,67] Egwu and Faull[68] describe rising serum and lacrimal antibody titers in sheep topically inoculated with *M. conjunctivae*. However, Trotter et al.[52] report low serum titers to *M. conjunctivae* in normal animals and no rise in titer in animals inoculated with *M. conjunctivae* subconjunctivally that subsequently developed signs of disease.

39.27.4 Epidemiology

Mycoplasmal infections apparently are transmitted directly from animal to animal, as evidenced by herd or flock outbreaks. The presence of carrier animals is postulated, and *M. conjunctivae* can be cultured from

unaffected animals.[69,70] Animals can become reinfected. Keratoconjunctivitis can be induced in sheep with topical inoculation of *M. conjunctivae*.[68,71,72] Clinical signs were identical to natural outbreaks and spread to uninoculated sheep. The organism can be cultured from eyes long after clinical signs abate.[59] See Chapter 38 for more details on *M. mycoides*.

39.27.5 Treatment and Prognosis

In most animals, mycoplasmal keratoconjunctivitis associated with *M. conjunctivae* is transient. Affected animals usually recover spontaneously in 10 days, although some animals seem to have recurring episodes that last for several weeks. In a controlled clinical trial, one dose (20 mg/kg) of long-acting oxytetracycline was given to experimentally inoculated lambs. This treatment seemed to hasten the cessation of clinical signs, although the results were not analyzed statistically.[73] The treatment did not, however, eliminate the *M. conjunctivae* infection. Other drugs recommended for the ocular disease include topical oxytetracycline or oxytetracycline and polymyxin B.[51] Subconjunctival oxytetracycline is not currently recommended because it may cause a severe inflammatory reaction. In vitro antibiotic testing of *M. conjunctivae* shows that tylosin, oxytetracycline, streptomycin, and chlortetracycline are suitable for treatment.[74]

Table 39-2 Major Infectious Ocular Diseases of Large Animals

Agent	Common Name/ Disease	Major Sign(s)	Cattle	Sheep	Goats	Horses
Mycoplasma conjunctivae	Pinkeye	Keratoconjunctivitis		++	++	
Mycoplasma mycoides subsp. *mycoides*	Pinkeye	Keratoconjunctivitis			+	
Acholeplasma oculusi (oculi)	Pinkeye	Keratoconjunctivitis		+	+	
Chlamydia psittaci	Pinkeye	Keratoconjunctivitis		++		
Branhamella (Neisseria)	Pinkeye	Keratoconjunctivitis		+	+	
Mycoplasma agalactiae		Keratoconjunctivitis		+	+	
Mycoplasma arginini		Keratoconjunctivitis		+	+	
Listeria monocytogenes		Keratoconjunctivitis	+	+		
Infectious bovine rhinotracheitis		Keratoconjunctivitis	++		+	
Colesiota (Rickettsia) conjunctivae	Pinkeye	Keratoconjunctivitis		+		
Equine viral arteritis		Keratoconjunctivitis				+
Equine herpesvirus type 2		Keratoconjunctivitis				+
Mycoplasma bovoculi		Conjunctivitis	+			
Ureaplasma species		Conjunctivitis	+			
Equine adenovirus		Conjunctivitis				+
Moraxella species		Conjunctivitis				+
Streptococcus equi	Strangles	Conjunctivitis				+
Moraxella bovis	Pinkeye	Corneal ulcer	++			
Equine herpesvirus type 1	Rhinopneumonitis	Keratitis				+
Malignant catarrhal fever		Uveitis, keratitis	+			

Neonatal septicemia		Uveitis	+	+	+	+
Mycobacterium bovis	Tuberculosis	Uveitis	+			
Salmonella species		Uveitis				+
Borrelia burgdorferi	Lyme disease	Uveitis				+
Leptospira interrogans		Recurrent uveitis				+
Brucella abortus		Recurrent uveitis				+
Scrapie		Retinitis		+		
Histophilus somni (Haemophilus somnus)	Infectious thromboembolic meningoencephalitis	Retinitis	+			
Bovine viral diarrhea		Retinal dysplasia, cataracts	+			
Bluetongue		Chorioretinitis, conjunctivitis	+	+		
Toxoplasma gondii		Chorioretinitis				+
Rhodococcus (Corynebacterium) equi		Panophthalmitis				+
Bovine leukemia virus		Exophthalmos	+			
Cryptococcus neoformans		Exophthalmos				+

39.27.6 Prevention and Control

Introduction of new animals into a herd or flock has been implicated in starting an outbreak of keratoconjunctivitis. Therefore, isolation and, if necessary, treatment of new animals are important before contact with the herd. No other specific recommendations have been made for prevention and control of *M. conjunctivae*. See Chapter 38 for control of *M. mycoides* subsp. *mycoides*.

39.28 CHLAMYDIAL KERATOCONJUNCTIVITIS IN SHEEP

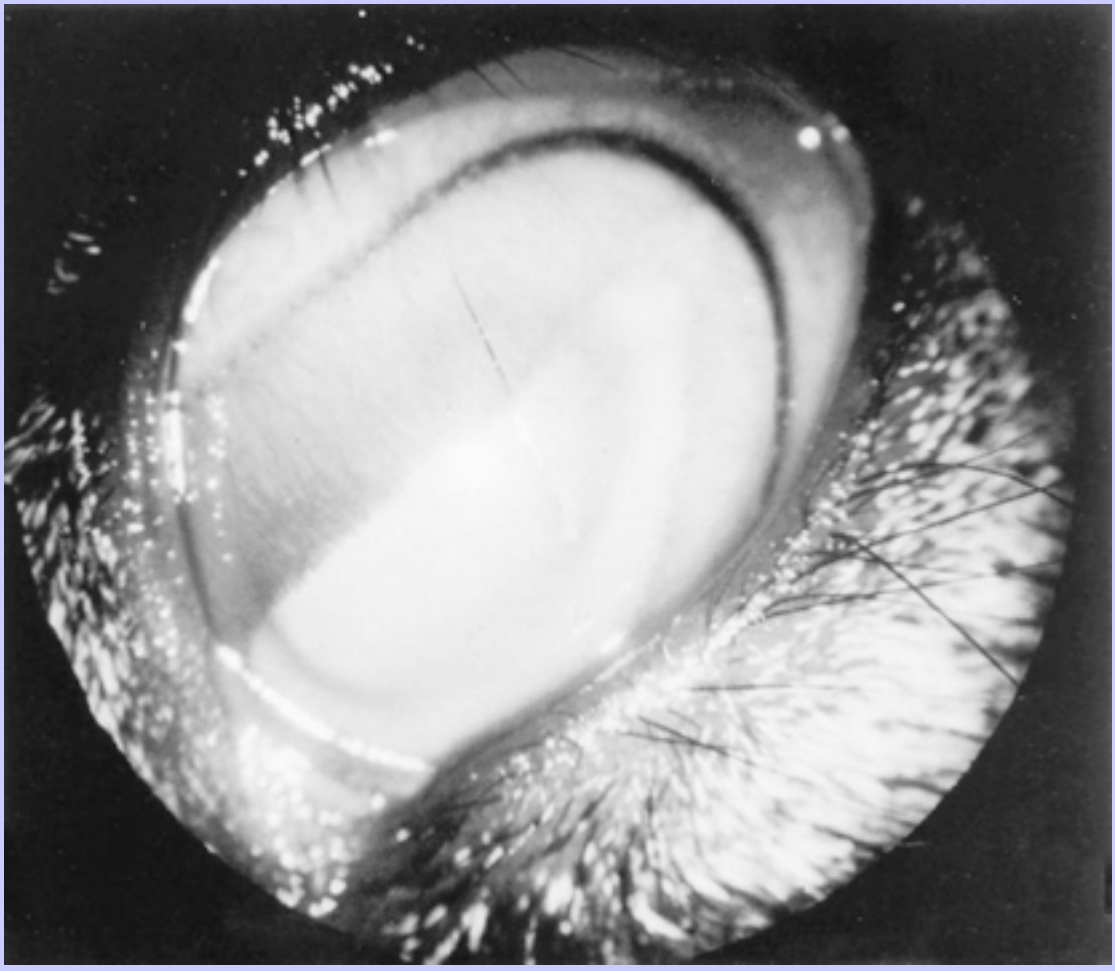
39.28.1 Definition and Etiology

Chlamydial agents have been isolated from outbreaks of keratoconjunctivitis in sheep flocks. The agent was originally described as a strain of *Chlamydia psittaci*. The agent is now called *Chlamydophila pecorum,* which can also cause abortion (see Chapter 43) and polyarthritis (see Chapter 38) in lambs.[75,76]

39.28.2 Clinical Signs and Differential Diagnoses

Early clinical signs consist of epiphora, chemosis, and conjunctival hyperemia. Later in the disease, follicle formation in the conjunctiva becomes prominent. Still later, corneal neovascularization may be seen. Most cases are bilateral and symmetric.[77,78] In some flock outbreaks of keratoconjunctivitis, outbreaks of polyarthritis are also noted. Most lambs that develop chlamydial polyarthritis will also develop conjunctivitis.[77,78] Differentials include other infectious causes of keratoconjunctivitis, such as *Mycoplasma* and *Branhamella (Neisseria)* species, aerobic bacteria, and parasites, as well as noninfectious causes such as trauma. 1275 1276

Fig. 39-12 Left eye of goat with mycoplasmal keratoconjunctivitis. Note diffuse corneal edema and dorsally the marked corneal neovascularization.



39.28.3 Clinical Pathology

Early in the disease, conjunctival smears show numerous neutrophils and some lymphocytes. Later, there are more neutrophils and fewer mononuclear cells. Cytoplasmic chlamydial inclusions are occasionally seen in up to a third of the eyes scraped and can be definitively identified by fluorescent antibody staining.[75] Conjunctival epithelial cells are often necrotic. Chlamydial organisms can be cultured from conjunctival scrapings and from blood taken from sheep with polyarthritis and conjunctivitis.[77–79] In one study, titers to chlamydial antibodies were found at 1:16 or higher in a number of the affected lambs, although titers on normal lambs were not reported.[78] Polymerase chain reaction (PCR) can also be used to identify the organism.

39.28.4 Epidemiology

Chlamydial organisms are apparently transmitted by direct contact, as evidenced by flock outbreaks. Chlamydial organisms caused conjunctivitis in five lambs inoculated topically.[80] An uninoculated lamb housed with the five lambs also developed conjunctivitis. Lambs subsequently developed follicular conjunctivitis.[79] In another study, chlamydial organisms were injected intraarticularly, intravenously, and intramuscularly and caused polyarthritis and conjunctivitis.[79]

39.28.5 Treatment and Prognosis

In uncomplicated cases the disease is self-limiting, and eyes are normal within 2 to 3 weeks.[78] The same treatments indicated for *Mycoplasma mycoides* subsp. *mycoides* (systemic oxytetracycline and, when possible, a topical tetracycline ophthalmic preparation) are also effective in treating chlamydial conjunctivitis/polyarthritis of sheep.

39.29 *BRANHAMELLA (NEISSERIA) OVIS* KERATOCONJUNCTIVITIS IN SHEEP AND GOATS

Branhamella ovis is a gram-negative diplococcus similar to *Moraxella* species. This agent has been cultured from sheep and goats with keratoconjunctivitis;[81,82] however, it can also be cultured from normal eyes.[83] *B. ovis* has also been cultured from cattle with serous conjunctivitis and rarely keratitis.[84] Clinical signs are usually mild and include epiphora and conjunctival hyperemia.

In one outbreak, neutrophils and gram-negative coccobacilli were seen on conjunctival scrapings. *B. ovis* was cultured from the initial outbreak and was then instilled into the conjunctival sac of goats with or without ultraviolet radiation. The experimentally infected goats developed epiphora and conjunctivitis, but no keratitis.[85] In another study, *B. ovis* instilled into the conjunctival sac of lambs induced reddened conjunctiva and follicle formation. *B. ovis* could be cultured from these eyes for up to 20 days after inoculation.[86]

In one outbreak, animals were treated with parenteral tylosin and topical neomycin, polymyxin B, and a corticosteroid, and all 10 recovered.[81] Bankemper et al.[85] used subconjunctival penicillin to treat affected goats.

39.30 SCRAPIE-ASSOCIATED RETINOPATHY IN SHEEP AND GOATS

The scrapie agent causes a degenerative CNS disease in sheep and less often in goats. Barnett and Palmer[87] described two sheep with scrapie that also had multifocal hyperreflective areas in the tapetum, histologically seen as small areas of retina raised by an accumulation of eosinophilic material between photoreceptors and retinal pigment epithelium. The eosinophilic material was characterized as a complex lipid. It was not shown that scrapie had caused the lesions.[87] Subsequently, using a monoclonal antibody, a goat with natural scrapie was found to have the scrapie prion protein in the retina without any microscopic retinal lesions.[88] A sheep experimentally infected with scrapie was also found to have prion proteins in the retina,[89] as was a sheep experimentally infected with the prion responsible for bovine spongiform encephalopathy (BSE).[90] Prion proteins can also be found in the nictitating membrane,[90,91] which may permit the antemortem diagnosis of scrapie. (See Chapter 35 for more information on scrapie.)

39.31 BLUETONGUE-INDUCED RETINAL DYSPLASIA IN SHEEP AND CATTLE

Bluetongue is a disease of ruminants caused by an arbovirus that is transmitted by *Culicoides* gnats. Clinical signs include fever and vasculitis that leads to oral lesions, lameness, swollen face, pulmonary edema, and death (see Chapter 32). In pregnant ewes vaccinated with modified live virus (MLV) on day 40 of gestation, fetuses developed cerebral anomalies.[92] These anomalies have also been described in clinical cases in which ewes had been vaccinated with MLV at about 5 or 6 weeks of gestation. In addition, when the fetus was vaccinated with MLV vaccine between days 50 and 75 of gestation, lesions of retinitis and choroiditis were noted that appeared centered around retinal vessels. In some eyes, inflammatory lesions produced persistent areas of retinal dysplasia.[93]

39.32 LISTERIA MONOCYTOGENES IN SHEEP, CATTLE, AND HORSES

Listeriosis in ruminants is manifested mainly as either an encephalitis or as a septicemia in neonates, or as a reproductive problem manifested as abortions. Ocular signs with the neural form include facial paralysis and ptosis, often unilateral, on the side of the central lesion; medial strabismus, often on the ipsilateral side because of involvement of the abducens nucleus; nystagmus; and amaurosis.[94] Uveitis with hypopyon has been described in chronic cases.[95]

1276 1277

Listeria monocytogenes has been cultured from conjunctival smears taken from sheep and cattle with keratoconjunctivitis.[96] In most of the sheep, *Branhamella (Neisseria) ovis* was also cultured. Clinical signs included conjunctival hyperemia, epiphora, photophobia, and corneal opacification. Treatment with topical chlortetracycline was curative. Walker and Morgan[97] provide a description of two experimental sheep that developed unilateral anterior uveitis. *L. monocytogenes* was cultured from the conjunctiva of each animal. Both animals recovered after treatment with parenteral ampicillin and topical antibiotics. *L. monocytogenes* has been cultured from the conjunctiva of three cows with keratitis (one with keratitis and uveitis) and from a corneal scraping of one horse with keratitis.[98] In another case report, *L. monocytogenes* was cultured from the cornea of a horse with chronic keratitis.[99] Diagnosis is usually achieved by isolation of *L. monocytogenes* from tissues at necropsy. Early treatment with broad-spectrum antibiotics may be effective in some cases.

39.33 INFECTIOUS BOVINE RHINOTRACHEITIS KERATOCONJUNCTIVITIS IN GOATS

Goats are susceptible to infectious bovine rhinotracheitis (IBR) virus, which in some cases may result in ocular disease. In one goat with ocular signs, conjunctivitis and keratitis with keratoconus were seen 5 days after the onset of severe respiratory illness. IBR virus was isolated from ocular and nasal discharge.[100]

39.34 *COLESIOTA (RICKETTSIA)* KERATOCONJUNCTIVITIS IN SHEEP

Colesiota (or *Rickettsia*) *conjunctivae* has been described as the cause of infectious keratoconjunctivitis in sheep, but documentation is sparse. The organism has not been cultured; only identified on conjunctival scrapings. Clinical signs include epiphora, conjunctival hyperemia, and corneal neovascularization.[101] Several authors have since suspected that this organism is the same as *Chlamydia psittaci* (now known as *Chlamydophila pecorum*).[102,103]

39.35 INFECTIOUS BOVINE RHINOTRACHEITIS CONJUNCTIVITIS

39.35.1 Etiology

IBR is a herpesvirus that may involve the respiratory or reproductive tracts, nervous system, or conjunctiva or may cause widespread systemic disease (see also Chapter 31). Conjunctivitis is the most common ocular manifestation of the disease, and it may occur as an isolated clinical entity or with involvement of other body systems.[104–106]

39.35.2 Clinical Signs and Differential Diagnoses

Although conjunctivitis is frequently bilateral, it can be unilateral. Ocular discharge; initially serous and later becoming mucopurulent, is usually seen without blepharospasm. Chemosis may be severe, especially by 1 week after infection. Both the palpebral and the bulbar conjunctiva are injected, and petechial hemorrhages may occur. Multiple white plaques 0.2 to 0.5 mm in diameter may develop on the palpebral and, to a lesser extent, the bulbar conjunctival surfaces at 1 to 2 weeks after onset of clinical signs. These may coalesce later in the disease (5 to 9 days). Corneal vascularization and perilimbal edema and opacification occur in severe cases. Iridocyclitis (seen as miosis) may occasionally occur in severe cases.

Corneal changes of IBR are differentiated from those of infectious bovine keratoconjunctivitis (IBK) caused by *Moraxella bovis* by their peripheral rather than central distribution and lack of corneal ulceration in IBR, unless IBR and IBK occur concurrently in the same eye (see later IBK section). Corneal vascularization and opacification in malignant catarrhal fever accompany marked signs of anterior uveitis[107] and other signs of generalized vasculitis.

Although ocular disease may occur as an isolated entity, ocular signs may be found in animals with upper respiratory tract signs, including rhinitis and dyspnea. Affected animals may be pyrexic, and a fall in milk yield may occur. Abortion in pregnant animals may occur following ocular manifestations of the disease.

39.35.3 Diagnostic Procedures

IBR can be recovered from infected eyes during the first 7 to 9 days of the disease but infrequently thereafter. Swabs may be taken for viral isolation in cell culture, which is probably the most reliable means of making a definitive diagnosis. Fluorescent antibody techniques may be used on conjunctival scrapings, and serology may be helpful if blood samples can be collected during the acute and convalescent stages of the disease. PCR is also being used. Histopathology to detect intranuclear inclusions is not likely to allow reliable diagnosis of the disease.[107,108]

39.35.4 Pathophysiology

Specific strains of the virus usually cause only one form of the disease (e.g., ocular form) in a herd. Ocular infection results in lymphoid hyperplasia, visible as white plaques. On histology, these are composed of plasma cells and lymphocytes in the conjunctival stroma and subepithelial area. Mild conjunctival epithelial ulceration may occur. During the recovery phase of the disease, diphtheritic membranes secondary to conjunctival necrosis develop on the conjunctival surface.

39.35.5 Treatment and Prognosis

Recovery from the conjunctival form of the disease is spontaneous within 10 to 20 days. In certain situations, palliative treatment may be helpful. This is achieved by cleaning the ocular discharge from the lids and applying a topical broad-spectrum antibiotic to prevent secondary bacterial infection. Treatment of the conjunctival form of the disease with topical antiherpetic agents has not been studied and would rarely be practical or cost-effective.

39.35.6 Prevention and Control

Vaccination of susceptible animals is the most effective means to prevent and control the disease. IBR vaccination programs are discussed in Chapter 48.

39.36 MALIGNANT CATARRHAL FEVER KERATOCONJUNCTIVITIS

Malignant catarrhal fever (MCF) is a sporadic disease characterized by fever, lymphadenopathy, and generalized vasculitis resulting in inflammation of the mucosal membranes of the mouth, nose, and eye; the skin; and the gastrointestinal (GI) and nervous systems, with variable but usually high mortality. The African form is caused by alcelaphine herpesvirus type 1. The North American form is caused by a similar virus, ovine herpesvirus.[109,110]

1277

Various forms of the disease are described on the basis of clinical signs (see Chapter 32). Ocular involvement is seen in the acute “head and eye” form, which is the most common presentation of the disease. Ocular signs include photophobia, epiphora, episcleral injection and scleritis, severe conjunctivitis, keratitis (corneal opacification caused by edema and vascularization appearing perilimbally), anterior uveitis, and exophthalmia. Less significantly, and difficult to diagnose clinically, retinal vasculitis may develop. Bullous keratopathy may develop as a result of edema in the anterior cornea, with subsequent rupture of bullae to form painful corneal erosions.[111] The absence of central corneal ulceration distinguishes the disease from IBK, and the severity of the ocular lesions is worse than would be expected in IBR, bovine viral diarrhea/mucosal disease (BVD/MD), or

1278

bluetongue. Differentiating this disease from Rinderpest could be clinically difficult in areas where both are endemic in cattle.

Serology and PCR are being used to confirm the clinical diagnosis.[112,113] The ocular lesions are those of a nonsuppurative uveitis and vasculitis. The lesions involve the conjunctiva, cornea, anterior uvea, and retinal blood vessels; the choroid is rarely involved. Serofibrinous and cellular infiltrates develop in the uvea and retina as a result of vasculitis and thrombosis. Perivascular cuffing and optic neuritis may be detected histologically.[114–116]

Prognosis for the eyes and the animal's recovery is poor.[111] Most importantly, in endemic areas, cattle should be kept away from sheep, which may act as a reservoir for the disease, and affected animals should be isolated.

39.37 BOVINE MYCOPLASMAL CONJUNCTIVITIS

Mycoplasma bovoculi and *Ureaplasma* species have been isolated from cattle with conjunctivitis and IBK. Inoculation of normal calves with *M. bovoculi* or *Ureaplasma* isolates produced conjunctivitis characterized by serous discharge and localized to diffuse conjunctival hyperemia. Experimentally induced conjunctivitis ran a course of over 1 month. Cases can be confirmed by culture or PCR performed on conjunctival swabs.[117] Mycoplasmal infection may predispose the animals to development of IBK from *Moraxella bovis*[118,119] (see later IBK section). Therefore, although treatment of mycoplasmal conjunctivitis per se may not be warranted, it may be advisable in areas where IBK is endemic. Topical oxytetracycline ointment applied three times daily or intramuscular (IM) injection of long-acting oxytetracycline is recommended.

Other mycoplasmal organisms (e.g., *M. arginini*) can be isolated from cows' conjunctiva but are not thought to cause the disease. *M. bovis* was found using PCR performed on normal conjunctival samples,[117] but it was not thought to cause conjunctivitis. *M. bovigenitalium, M. bovirhinis,* and *M. bovoculi* were isolated from members of two cattle herds with conjunctivitis and bronchopneumonia.[120] However, when viral cultures were performed, IBR was isolated in the same individuals. The mycoplasmal organisms may have contributed to the disease in these herds. In another cattle herd with outbreak of respiratory disease, keratoconjunctivitis followed, and *M. bovis, M. bovirhinis,* and *M. bovoculi* were isolated in various combinations from affected calves.[121]

39.38 *HISTOPHILUS SOMNI* CONJUNCTIVITIS AND RETINITIS

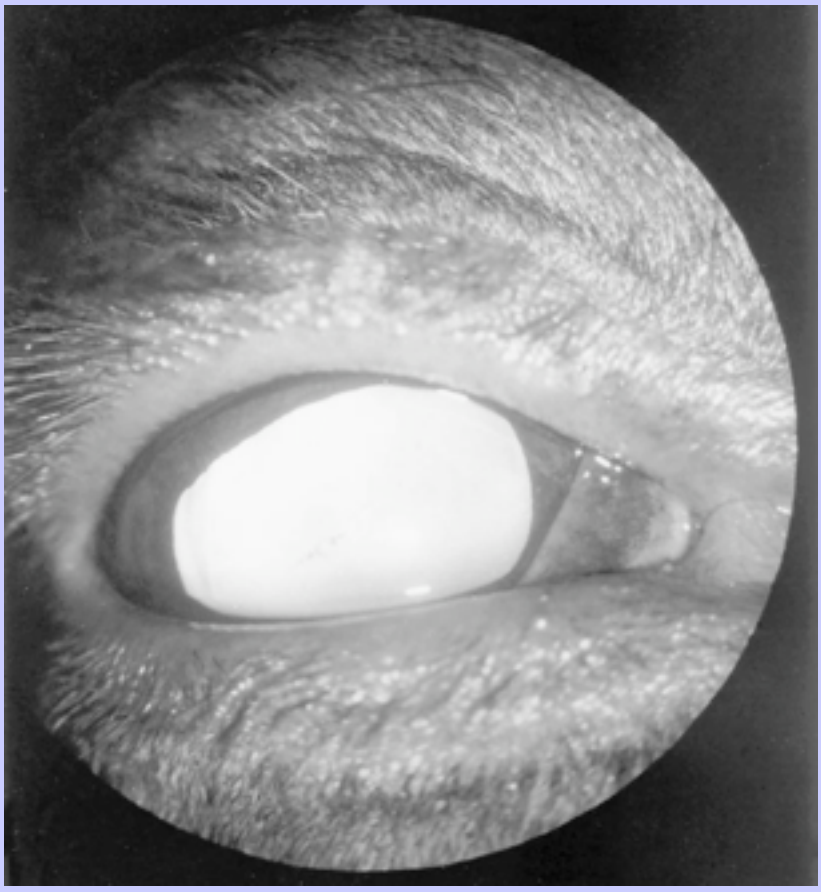
Thromboembolic meningoencephalitis (TEME) is a fatal septicemia caused by infection with *Histophilus somni* (see Chapter 35). Calves and young adult cattle can be affected, but the disease most often occurs in feedlot cattle less than 1 year of age. The organism is capable of damaging vascular endothelial cells and activating blood clotting. Therefore, most of the ocular histologic signs are referable to thrombosis of retinal vessels.

Although conjunctivitis may be seen, the main ocular findings are in the fundus. Retinal hemorrhages and exudates may be focal or diffuse. Retinal infiltrates may elevate the retina and involve the vitreous. Retinal edema, hemorrhage and necrosis, vascular thrombosis, and infiltration of the retina and vitreous with neutrophils are seen histologically. Eosinophilic cytoid bodies (swollen axons) are seen in the nerve fiber layer of the retina. Retinal detachments may result from retina edema. Later in the disease, areas of chorioretinitis result in chorioretinal scars. The anterior segment is less involved in this disease than in MCF, in which keratitis and anterior uveitis are usual.[122,123]

39.39 BOVINE VIRAL DIARRHEA—INDUCED RETINAL DYSPLASIA, CATARACTS, MICROPHTHALMIA, OPTIC NEURITIS, AND LEUKOCORIA

The causative agent of bovine viral diarrhea (BVD) is a pestivirus (part of the togavirus group; genus *Pestivirus,* family Togaviridae) that, in congenitally affected animals, causes retinal inflammation and necrosis. Cattle infected between days 75 and 150 of gestation may produce calves with cerebellar hypoplasia or ocular lesions. Calves with ocular signs may be blind, and nystagmus may be present. Pupillary light reflexes may or may not be absent. Other abnormalities may include microphthalmia, cataract, leukocoria (either as a result of cataract or dense white inflammatory infiltrate in the anterior vitreous; Fig. 39-13), retinal hemorrhages, chorioretinitis, retinal dysplasia or folds, retinal detachment, or optic neuritis or atrophy.[124–127] The optic disc may appear atrophic, and areas of tapetal color change and hyperreflectivity may be seen, with retinal vascular attenuation. In some cases, inflammatory debris may persist in the vitreous after birth, precluding adequate fundic examination. Congenital cataracts also occur in this disease, and although the pathophysiology is unknown, they probably develop secondary to the intraocular inflammation and necrosis. Cataracts mainly involve the lens cortex. 1278 1279

Fig. 39-13 Leukocoria (white pupil) in a Simmental calf caused by inflammatory debris in the vitreous and on the posterior capsule of the lens after intrauterine infection with bovine viral diarrhea.



Transplacental infection may occur when the dam is infected during pregnancy. The severity of the disease is related to fetal age at the time of intrauterine infection. Severe fetal disease and often fetal death occur in cattle infected between 100 and 200 days of gestation. Infected fetuses can also survive and become persistently infected with the virus. In these cattle, viral antigens can be found in neurons of the retina and CNS in the absence of clinical signs.[128] Ocular discharges have been reported in cases of acute or chronic cases of BVD, although the significance of these observations is uncertain.[127,129]

Serum samples collected from affected calves before ingestion of colostrum can be submitted for serologic assessment using the serum-virus neutralization test, or virus isolation can be attempted from buffy coat cells of a whole-blood sample collected into EDTA. (See Chapter 32.)

39.40 BLUETONGUE CONJUNCTIVITIS

Conjunctivitis and mucopurulent ocular discharge may be seen in cattle chronically infected with bluetongue virus. Although topical antibiotics could be applied to reduce secondary bacterial infection and reduce the ocular discharge, this would rarely be necessary.[130]

39.41 BOVINE LEUKOSIS AS A CAUSE OF EXOPHTHALMOS

Lymphosarcoma in adult cattle is usually caused by bovine leukemia virus, although noninfectious sporadic cases are reported in young animals. Lymphosarcoma may result in unilateral or bilateral progressive exophthalmos.[131,132] This is the most common orbital neoplasm in cattle. If undiagnosed, exposure keratitis and chemosis develop. Intraocular involvement can occur, although it is less common than orbital neoplasia. Generalized lymphadenopathy or other signs of generalized lymphosarcoma usually accompany the orbital form. Specific serologic tests will confirm the diagnosis. Enucleation or exenteration is rarely indicated because of the poor prognosis for affected animals. Differential considerations for progressive exophthalmos include frontal or maxillary sinusitis or nasal neoplasia, actinomycosis, and actinobacillosis.

39.42 OCULAR MANIFESTATIONS OF TUBERCULOSIS

Tuberculosis caused by *Mycobacterium bovis* may cause granulomatous lesions in the eye of affected cattle. The uveal tract (iris, ciliary body, or choroid) is initially affected, with later expansion of granulomas into other ocular structures. Uveitis, keratitis, and chorioretinitis with retinal detachment are seen clinically.[133]

39.43 OCULAR MANIFESTATIONS OF NEONATAL SEPTICEMIA

Neonatal septicemia in calves, foals, lambs, and kids may occur in the first few weeks after birth and may arise from umbilical infection or oral intake of bacteria (see Chapter 18). Septicemia is especially common in colostrum-deprived neonates. Secondary meningitis, polyarthritis, uveitis, and chorioretinitis may develop. Ocular signs include miosis, aqueous flare with fibrin deposition in the anterior chamber, hypopyon or hyphema, and in severe cases, panophthalmitis. Bacteria involved include *Escherichia coli, Streptococcus* species, *Pasteurella* species, *Salmonella* species, *Rhodococcus equi, Corynebacterium pyogenes,* and *Klebsiella* species. The incidence of infection with different bacteria varies among the domestic species. Therapy should include systemic antibacterial agents (based, when possible, on sensitivity testing) and treatment for uveitis. Prognosis for cases treated early is still guarded.[134–137]

39.44 BACTERIAL KERATITIS IN HORSES

39.44.1 Definition and Etiology

Bacterial keratitis occurs when a traumatic corneal ulcer becomes infected with opportunistic bacteria; no bacteria are known to *initiate* ulcers in horses. The most devastating clinical manifestations are associated with *Pseudomonas aeruginosa* and *Streptococcus equi* subsp. *zooepidemicus*. Additional bacteria isolated from infected corneas include nutritionally variant streptococci,[138] *Staphylococcus* species, *E. coli, Acinetobacter* species, *Clostridium* species,[139] *Corynebacterium* species, and others.[140,141]

39.44.2 Clinical Signs and Differential Diagnoses

Whether infected or not, corneal ulcers cause signs of pain (blepharospasm, epiphora, apparent photophobia). The conjunctiva is hyperemic, and the ulcerated area of the cornea retains fluorescein stain. A deep ulcer (resembling a crater in the corneal stroma) should be assumed to be infected. Superficial ulcers, on the other hand, are usually not infected, and the cornea maintains its normal curvature in the ulcerated area. Other signs of an infected ulcer are rapid progression and white or yellowish opacity of the cornea (signifying corneal stromal influx of neutrophils and bacterial colonization). An ulcer that is rapidly becoming wider or deeper or a "melting" ulcer, in which corneal stroma liquefies (Fig. 39-14), is highly suggestive of a bacterial infection. Fungal keratitis can appear similar but usually has a more insidious, or at least a slower, course. However, a cornea with fungal keratitis can become secondarily infected with bacteria. Bacterial keratitis can also present as a stromal abscess.[142] In these cases a cellular infiltrate is seen in the corneal stroma over which the initially damaged epithelium has healed. Therefore, such lesions do not stain with fluorescein, and many topical antibiotics cannot reach the site of infection.

Fig. 39-14 Right eye of horse with a melting corneal ulcer caused by *Pseudomonas* infection. Corneal stroma has liquefied and is overlying the lower lid.

39.44.3 Clinical Pathology

A diagnosis of a bacterial keratitis is made using Gram-stained corneal scrapings. Stained scrapings usually show many bacteria (some intracellular) and many neutrophils (some degenerate). Bacterial organisms are definitively identified after culture of the ulcerated cornea.

39.44.4 Pathophysiology

Bacterial keratitis is the result of pathogenic or opportunistic organisms colonizing a damaged cornea. The cornea is most likely to be damaged by mechanical trauma, but chemical damage is seen occasionally. Many different types of bacteria can be cultured from a normal eye, including *Corynebacterium, Streptococcus*, *Staphylococcus, Bacillus,* and rarely *Pseudomonas* species or other gram-negative bacteria.[143,144] Damage to the epithelium enables bacteria to adhere to the exposed corneal stroma and begin replicating.[145] Some bacteria

such as *Pseudomonas* elaborate collagenases and other proteoglycanolytic enzymes,[146] which results in corneal melting. Proteases and collagenases liberated by white blood cells and possibly corneal epithelial and stromal cells also contribute to the melting process. In this way, what begins as a small wound to the cornea can progress to a corneal perforation within 24 to 48 hours.

39.44.5 Treatment and Prognosis

Prognosis is guarded for any corneal ulcer that is rapidly progressing or melting. These ulcers can easily progress to corneal perforation and loss of the eye despite timely, appropriate treatment. On the other hand, with vigorous therapy some eyes with infected ulcers can be saved, leading to a visual eye, although usually a permanently scarred cornea.

In any ulcer in which a bacterial component is suspected, C&S of the ulcer and a corneal scraping for Gram staining and cytology should be taken. The horse is restrained or sedated, a palpebral block performed, topical anesthetic applied to the cornea, and a culture of the ulcer taken with a moistened swab. The ulcer margins are then scraped with a Kimura spatula or the blunt, handle end of a scalpel blade.

In cases of equine bacterial keratitis, including stromal abscesses, the therapeutic goals are to eliminate the bacteria, prevent or slow melting if present, and treat the concurrent uveitis. Because this requires very frequent applications of numerous medications to a horse with a painful and often fragile eye, a subpalpebral lavage system is usually required.

39.44.5.1 PLACEMENT OF SUBPALPEBRAL LAVAGE SYSTEM

The following equipment is necessary:

- Subpalpebral lavage kit (Fig. 39-15)
- White tape
- Applicator stick
- Lidocaine
- Topical ophthalmic anesthetic (proparacaine)
- Monofilament nonabsorbable suture on a cutting needle
- Tetanus toxoid

The horse should be tranquilized and/or twitched. The auriculopalpebral nerve is blocked over the zygomatic arch to paralyze the orbicularis oculi muscle and reduce spontaneous eyelid movement. The supraorbital (frontal) nerve is blocked at its exit from the supraorbital process to anesthetize the upper eyelid (Fig. 39-16). Topical anesthetic (proparacaine) is then applied to the eye by directing a gentle stream into the upper conjunctival fornix with a small syringe with a broken-off 25-gauge needle.

The blunt end of the 12-gauge needle is used to probe the lateral conjunctival fornix to establish the placement of the needle. The needle then is reversed and pushed through the eyelid in a lateral direction using a pair of needle holders as resistance (Fig. 39-17). The tip of the needle enters the dorsalmost aspect of

the fornix and exits near the orbital rim (Fig. 39-18). After the needle is pushed through the skin (Fig. 39-19), the Silastic Mila tubing is pushed through the needle, starting at the blunt end. When the tubing appears at the sharp end of the needle, the needle and tubing are pulled through the eyelid (Fig 39-20). The tube is then pulled up until the footplate fits snugly up into the dorsal conjunctival fornix (Fig. 39-21). During the manipulations, care must be taken to ensure that the needle or the hands of the operator do not push against the cornea.

1280

1281

Fig. 39-15 Subpalpebral lavage kit (Mila International Inc.)

Fig. 39-16 Frontal (supraorbital) nerve block in horse. A 25-gauge needle is inserted into the supraorbital foramen, and 5.0 mL of lidocaine is injected alongside the nerve.

Fig. 39-17 The 12-gauge needle is pushed through the eyelid with open needle holders used as resistance and to keep the eyelid skin from tenting.

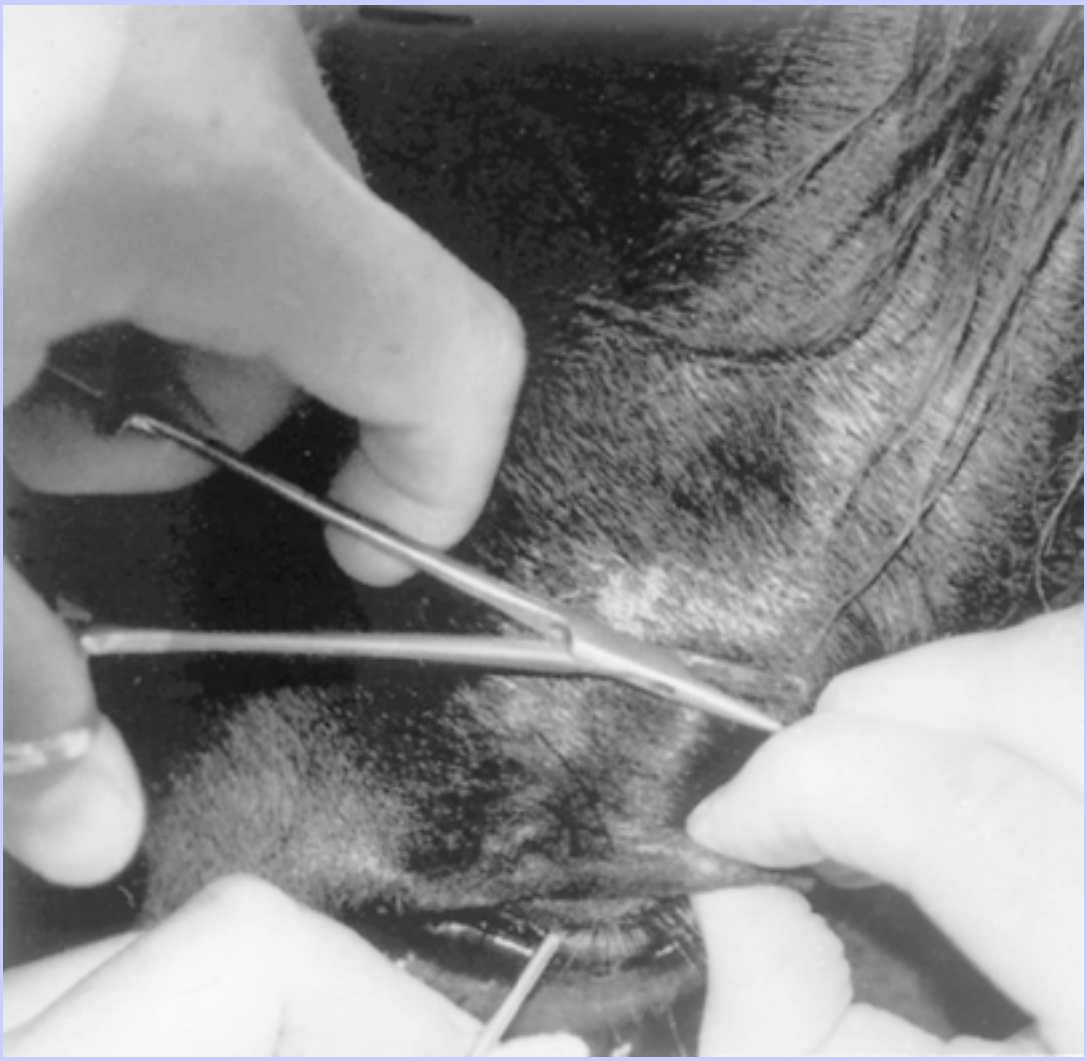


Fig. 39-18 Preparing to push the 12-gauge needle with a gauze sponge before placing a palpebral lavage system.

Tape is used to secure the tubing to the upper eyelid, and sutures secure the tape to the skin (Fig. 39-22). Alternatively, the green-plastic securing device in the pack can be sutured near the exit hole, securing the tubing without putting tape on the tubing. Additional tape and skin sutures can be placed several centimeters from the first tape, or tubing can be braided through the forelock. The Silastic tubing is then run down the neck through several braids to keep it secure. A catheter is run into this distal end of the tubing, an injection port is fixed to the end of the catheter, and the catheter and tubing are taped to an applicator stick to prevent kinking. The stick is then taped to a braid of the mane.

Fig. 39-19 Correct orientation of the 12-gauge needle as it is advanced through the upper lid from deep in the dorsal conjunctival fornix to exit near the orbital rim. Needle pushed through the eyelid laterally. Note that the needle was inserted 45 degrees to the eyelid margin. The lavage system is now threaded through the needle and the needle removed.

Fig. 39-20 The 12-gauge needle is withdrawn dorsally from the upper eyelid and the lavage tubing pulled through until the footplate is snug in the dorsal fornix.

Poorly placed lavage tubes or tubes that slip ventrally can rapidly produce a corneal ulcer. A displaced tube footplate can also cause topical medications to leak into the subcutaneous tissues, rapidly leading to a swollen and inflamed eyelid. Therefore the tube position should be checked at least once daily by gentle dorsal traction on the exposed tubing to ensure it has not slipped into the conjunctival cul-de-sac. Excess traction will pull the footplate through the conjunctiva and into the eyelid itself. Most horses tolerate this system well, and we have kept the tubing in place for up to 6 weeks. Occasionally, horses try to rub their heads and can damage the tubing; neck cradles or protective eye cups can be used in such horses. 1281 1282

Fig. 39-21 Footplate of the subpalpebral lavage kit.

Fig. 39-22 Subpalpebral lavage system secured in final position with tape "wings" sutured to the skin.

39.44.5.2

MEDICAL/SURGICAL APPROACHES AND GOALS

In a cornea with rapidly developing keratitis or melting ulcer, the clinician should always suspect the presence of *Pseudomonas* organisms, although other organisms such as *Streptococcus* have also been described. Treatment should be started with an appropriate antibiotic used every 1 to 2 hours. Fluoroquinolones such as ciprofloxacin (Ciloxan, Alcon) and ofloxacin (Ocuflox, Allergan)[147] are good choices for treatment of *infected* ulcers. They are not necessary for bacterial prophylaxis in *uninfected* ulcers. If gram-positive organisms are seen on the corneal scraping, ticarcillin, cefazolin (Ancef), penicillin, or ampicillin can be used.[148,149] Cefazolin is mixed to a concentration of 55 mg/mL,[150] ampicillin to 10 mg/mL,[148] and penicillin G to 100,000 U/mL. If the ulcer continues to worsen, antibiotics should be changed on the basis of the initial sensitivity results, and corneas should always be recultured in these cases because organisms can become resistant to the first antibiotic used. For resistant organisms, sensitivity testing that gives minimum inhibitory concentration (MIC) may be very useful because higher drug concentrations are more readily and safely attainable in the cornea than in the systemic circulation.

Melting of the cornea can be treated with collagenase and protease inhibitors. Experimentally, these drugs were not always effective in reducing melting.[151] However, some ophthalmologists believe that these drugs are efficacious. Certainly the main goal of therapy should be to kill the microorganism that is elaborating the enzymes. Autologous serum, EDTA, or acetylcysteine can be used topically, as can systemic doxycycline (10 mg/kg orally twice daily),[137] for their antiprotease and anticollagenase activity.

Surgical therapy can also be used and may improve prognosis. Conjunctival pedicle grafts can be used to bring a blood supply and subconjunctival fibroblasts to deep corneal ulcers and possibly slow progression and aid stromal reconstruction[149] while still allowing medication to reach the site of the ulcer. A conjunctival graft allows observation of the cornea so that treatment can be changed as corneal health improves or if the cornea continues to deteriorate. A nictitating membrane “flap” should *not* be used in rapidly progressing or deep ulcers because it does not allow topical medication or observation of the cornea. In the presence of a third eyelid flap, topically applied medications fail to reach the cornea, worsening of the ulcer goes unnoticed, reculturing cannot be performed, and appropriate changes in therapy cannot be instituted.

A corneoconjunctival transposition using autologous tissue or a corneal graft (penetrating keratoplasty) using donor cornea is an excellent treatment to repair very deep ulcers, descemetoceles, and perforations if melting has ceased and the ulcers are sterile.[140,151,152] Other substances that can be substituted for cornea are porcine small intestinal submucosa,[153] equine amniotic membrane,[154] or bovine pericardium (Dura Guard, Synovis). Placement of any graft requires microsurgical instruments, techniques, training, and experience. Highly specialized techniques, such as keratectomy with a conjunctival graft, penetrating keratoplasty, posterior lamellar keratoplasty, or deep lamellar endothelial keratoplasty, are necessary to treat stromal abscesses.[155–158]

The initial desired response to appropriate therapy of a malacic ulcer is simply cessation of worsening of the ulcer. That is, the ulcer does not appear to be healing or shrinking but also is not becoming larger or deeper. This suggests that bacteria have been killed and tissue destruction has halted. Epithelium will then begin to grow down the sides of the ulcer, covering the stroma or Descemet's membrane, and blood vessels will slowly begin growing into the cornea from the limbus. Once reepithelialization is complete, new infection with microorganisms is unlikely. If surgery has not been performed, however, the area that had been

ulcerated will be (sometimes markedly) thinner than the surrounding stroma. Thickening of this area will occur by very slow reconstruction of stromal collagen by corneal fibroblasts ("keratocytes") or when corneal blood vessels fill the old ulcer bed. This can take weeks to months, and until this happens, the cornea is susceptible to traumatic rupture.

Another goal of therapy for an infected ulcer is inhibition of "reflex uveitis" associated with any corneal irritation and mediated by the trigeminal nerve. Topical atropine is used for this purpose because it decreases pain associated with ciliary body spasm and maintains pupil dilation, which reduces the chance of posterior synechia formation. Atropine should be applied to effect (i.e., until reduced pain or pupil dilation noted). This may be as frequently as every 1 or 2 hours initially but may soon be limited to once daily or once every other day. Because topical atropine is absorbed into the systemic circulation and is associated with altered GI motility, borborygmi and signs of colic should be assessed frequently. Topical or systemic NSAIDs also can be used to decrease corneal and uveal inflammation. However, these drugs do slow corneal neovascularization to some extent, and topical NSAIDs (as with corticosteroids) are contraindicated in infected ulcers.[159,160] Topical corticosteroids are sometimes recommended to reduce corneal vascularization and minimize scar formation once epithelialization is complete. However, corneal vascularization is a critical means by which corneal stroma (and strength) is re-formed, and topical corticosteroids hasten regression of granulation tissue, suggesting that this approach may not be wise. In fact, no evidence indicates that steroid administration decreases the final size of the scar, and steroids may compromise healing and predispose to corneal rupture.

1282

1283

39.44.5.3 FUNGAL KERATITIS IN HORSES

39.44.5.3.1 DEFINITION AND ETIOLOGY

Fungal keratitis (or keratomycosis) occurs when an ulcerated cornea becomes infected with a mycotic organism. As with bacteria, no fungi are known to *initiate* corneal ulcers. The most common genera isolated in cases of equine fungal keratitis are *Aspergillus* and *Fusarium* species, but *Cylindrocarpon destructans* and *Phycomycetes, Penicillium, Paecilomyces, Candida, Mucor, Alternaria,* and species of other genera have been cultured.[161–165] Horses seem to be unusually susceptible to fungal keratitis compared with the other domestic species.

39.44.5.3.1.1 Clinical Signs and Differential Diagnoses

Fungal keratitis has various manifestations.[166] A common presentation is a corneal ulcer, often with a history of chronicity. Typical history is a nonhealing or worsening ulcer despite antibiotic and antiinflammatory therapy. The eye is painful; the conjunctiva is hyperemic; and blepharospasm, epiphora, and apparent photophobia are also present. Corneal edema and cellular infiltrates surround the ulcer. Sometimes the cellular infiltrates can be very dense and appear as a white or yellow area throughout the corneal ulcer. The cellular infiltrate can be deep in the cornea and in some cases on the endothelial surface of the cornea, or even protruding into the anterior chamber, because fungus has a predilection for Descemet's membrane in the horse cornea. Corneal neovascularization is usually seen (Fig. 39-23). Signs of secondary uveitis can be severe. If ulcerated, fluorescein will stain the cornea. In some cases of fungal keratitis, however, the epithelium heals over the fungal infection, forming a stromal abscess, and the cornea will not stain with fluorescein.

Fig. 39-23 Right eye of horse with fungal keratitis. Note corneal neovascularization and dense cellular infiltrates in the cornea.

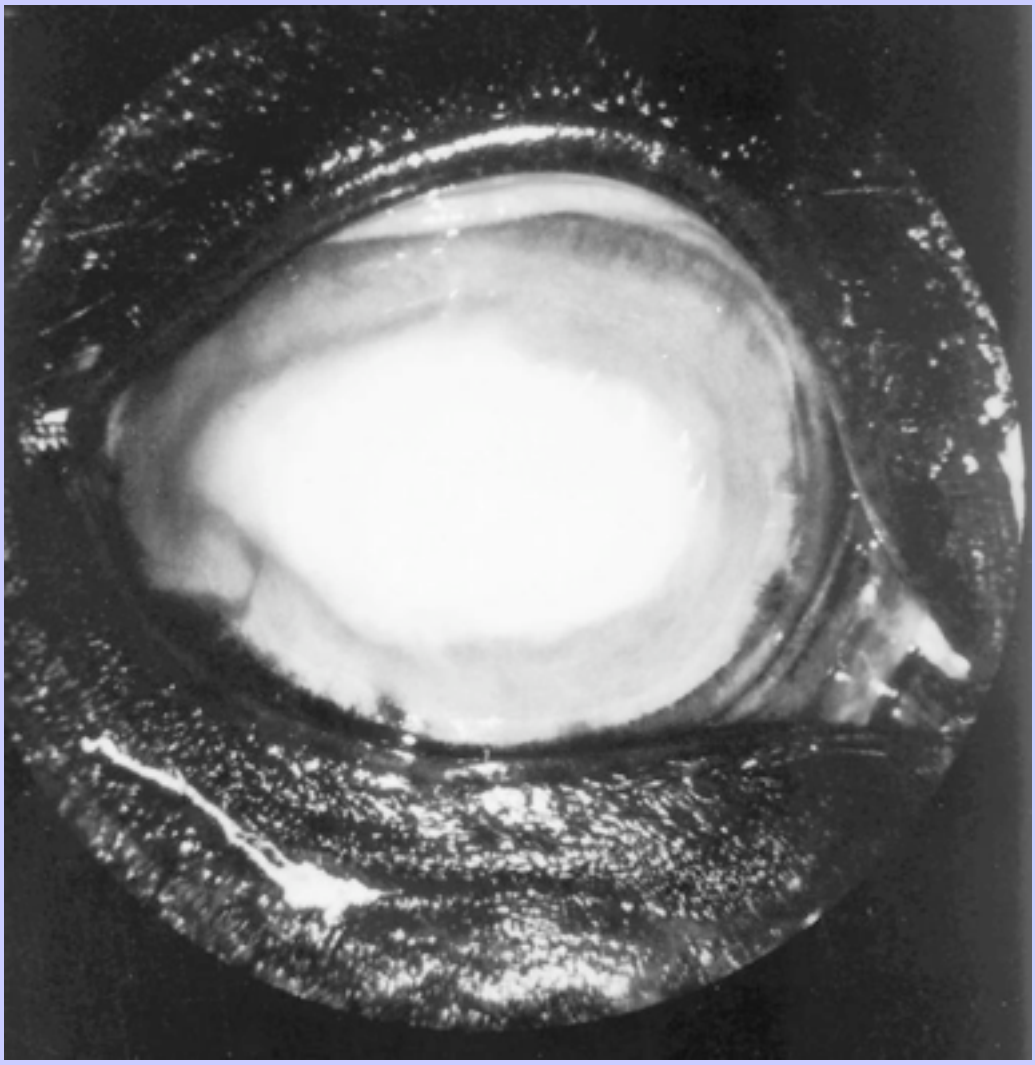

Fig. 39-24 Corneal scraping from horse with fungal keratitis. Note septate hyphae and surrounding inflammatory cells.

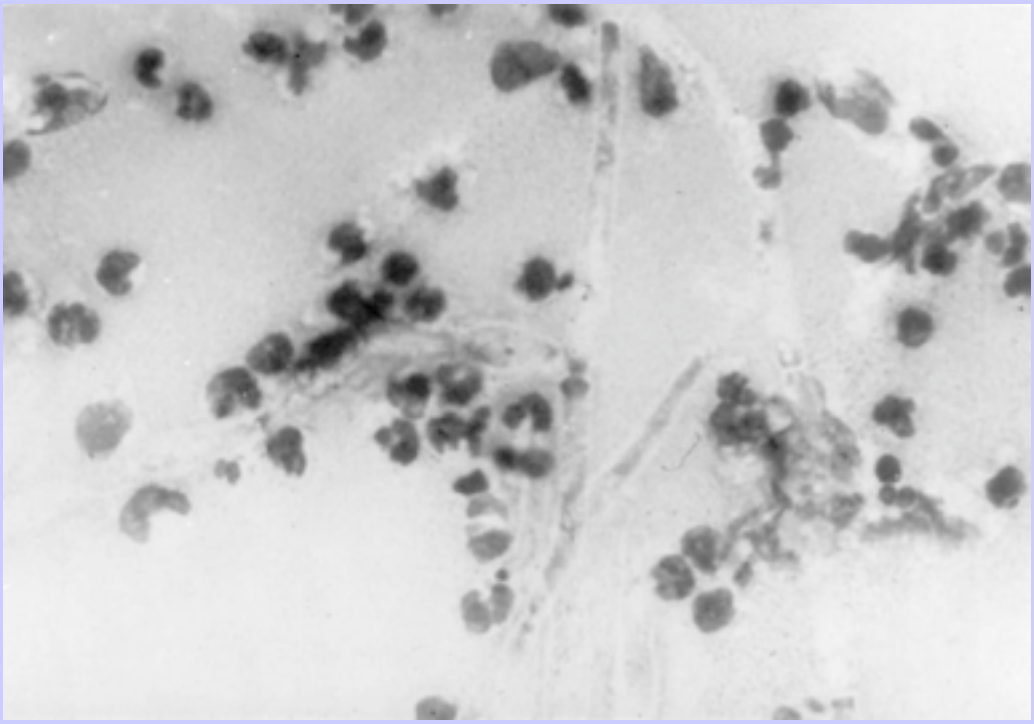

Fungal keratitis can also present as chronic, mild corneal disease. Small, multifocal, superficial opacities can be seen. In some cases there are small focal areas of fluorescein stain retention; sometimes there is no uptake of stain. Horses usually appear mildly painful with some epiphora; usually there is neither corneal neovascularization nor uveitis.

In all cases of fungal keratitis, differential diagnoses include other causes of corneal ulceration, such as bacteria (which may be coincident).

39.44.5.3.2

Clinical Pathology

A diagnosis of superficial fungal keratitis is made when fungal hyphae or yeast are seen on cytology or cultured from corneal scrapings (Fig. 39-24). Because fungi have a predilection for the deeper stroma and Descemet's membrane, a diagnosis of deep keratitis may require a full-thickness corneal biopsy from which the fungus is identified using culture or histopathology. Unfortunately, this predilection means some diagnoses of fungal keratitis are made only after enucleation.[167] If culture of an ulcer is positive when scrapings or biopsy do not show hyphae, the possibility of a commensal organism or incidental surface contaminant must be considered; especially if only one or two colony-forming units are cultured. Because treatment is prolonged and expensive, a definitive diagnosis of fungal colonization ideally should be made before treatment is initiated. The diagnostic utility of PCR for fungal keratitis is currently under investigation.

39.44.5.3.3

Pathophysiology

Fungal hyphae do not colonize intact cornea. Damage to epithelium is necessary for pathogenic or opportunistic fungi to begin growth in the corneal stroma. This usually results from a traumatic incident that may or may not be noticed by the owner. The use of antibiotics and corticosteroids alters normal flora and decreases the normal immune response, which may encourage fungal growth. Fungi implicated in keratomycoses are usually present in the horse's environment and can be cultured from more than 90% of normal horse eyes, with *Aspergillus* species being the most common isolate.[161] There is one report in the literature of keratomycosis caused by *Candida albicans* secondary to disseminated candidiasis.[168]

39.44.5.3.4

Epidemiology

This disease is sporadic, with varying seasonal distribution.[162,165]

39.44.5.3.5

Treatment and Prognosis

1283

Treatment consists of eliminating the fungus from the cornea and controlling secondary bacterial invasion and melting, along with reflex uveitis (if present), as for bacterial keratitis. Antifungal agents are required, and the course of treatment usually lasts for a number of weeks. Subpalpebral lavage systems are usually essential for delivering these drugs. Healing is usually not complete until corneal neovascularization has reached the infected area, except when the fungus has reached Descemet's membrane, and in these cases blood vessel growth does not always stop fungal growth. Medical therapy is most effective for treating superficial disease. For deep disease, surgical therapy can also be used with the medical therapy. Deep lamellar and penetrating keratoplasties probably carry the best prognosis,[150,155,167,169] although superficial keratectomies with a conjunctival graft can also be used for more superficial lesions.

1284

A number of antifungal agents are available. Miconazole, used as the undiluted IV preparation, was once the drug of choice for many ophthalmologists. Unfortunately, it is no longer available commercially in this formulation, although it can be compounded. Natamycin (Natacyn) is manufactured as an ophthalmic suspension and is the drug of choice for treating fungal keratitis in humans. However, natamycin does not penetrate intact epithelium well, and some *Fusarium* species may be resistant to this drug.[170] Fluconazole (Diflucan) is now often recommended as a replacement for miconazole. However, one study reported that fluconazole had lower in vitro activity than a number of other antifungal drugs.[171] The IV preparation is a 2 mg/mL solution, which is used undiluted as a topical preparation. Miconazole and fluconazole do penetrate intact corneal epithelium when given topically, but drug concentrations in the stroma are higher if epithelium is absent.[172] Fluconazole can also be used subconjunctivally, intracamerally, or intravitreally. Ophthalmologists are also beginning to use fluconazole systemically to treat deep corneal fungal disease because this drug does reach adequate concentrations in the aqueous humor, which may be appropriate for deep stromal or endothelial infections.[173] No toxicity studies have been performed on the horse, but anecdotal evidence does not suggest toxicities, and fluconazole has been associated with resolution of deep disease.

Compounded formulations of itraconazole/DMSO ointment have also been used for equine keratomycosis. High concentrations of itraconazole can be achieved in the corneal stroma with this preparation, even

when the overlying epithelium is intact, and it has been used successfully in clinical cases.[174] In contrast to fluconazole, systemically administered itraconazole does not penetrate normal equine eyes.[175]

Other drugs have been suggested as treatment for fungal keratitis. Voriconazole administered either topically or systemically does penetrate normal equine eyes and reaches concentrations that could be therapeutic.[176] Miconazole dermatologic or vaginal creams seem to work for mild, superficial disease; however, no clinical trials describing their efficacy and safety for ocular use have been reported. Amphotericin B has good antifungal properties but can be very irritating and is probably not the drug of choice. In vitro research shows that silver sulfadiazine is fungicidal against isolates from equine patients with keratomycosis.[170] Unfortunately, in vitro results do not necessarily correlate with clinical results in patients with keratomycosis. Corneal penetration of the drug, the horse's immune system, and the site and severity of the fungal infection all play important roles in choice of drug.[170]

In addition to the antifungal agent selected, topical mydriatic/cycloplegic agents such as atropine should be used to combat the accompanying uveitis, and topical antibiotics are indicated to prevent superinfection with bacteria. Systemic NSAIDs should be used for the secondary uveitis, especially at the beginning of treatment, when fungal death can exacerbate the uveitis. However, NSAIDs probably slow neovascularization of the cornea, and treatment with these drugs should be decreased as the uveitis is controlled.[177]

Prognosis is guarded to poor in many cases of fungal keratitis. Usually the best possible outcome is a visual eye with some degree of residual corneal scarring and possibly synechiae. Because no evidence suggests that corticosteroids decrease the eventual size of the scar, and because they will promote the presence of residual hyphae, the use of corticosteroids is not recommended in a healing fungal ulcer. Complications of fungal keratitis include perforation of the ulcer with loss of the eye, superinfection with bacteria, and phthisis bulbi.

39.44.5.4 UVEITIS ASSOCIATED WITH LEPTOSPIROSIS IN HORSES AND COWS

Leptospirosis is caused by a filamentous bacterium known as a spirochete. Disease is seen in most domestic animals as well as humans. Various serovars of *Leptospira interrogans sensu stricto*, *L. kirschneri*, and *L. santarosai* have been shown to affect various organs, such as kidneys, liver, spleen, muscles, CNS, and eyes and have been associated with abortions.[178] These organisms primarily cause a vasculitis and endotheliitis in these organs.[179]

Because leptospiral organisms cause vasculitis, it is reasonable to assume that uveitis might be present in an acute infection, and this has been reported in horses during the acute phase of leptospirosis.[180] Uveitis has also been seen experimentally in a calf during acute disease.[181] However, the role of leptospires in uveitis seen weeks to months after the acute disease remains much more controversial. Evidence for such a role is most complete in the horse, in which leptospiral uveitis and its role in equine recurrent uveitis (ERU) or “periodic ophthalmia” have been described.[180,182,183] Uveitis in these horses was bilateral or unilateral and frequently was recurrent, leading to loss of or decrease in vision.[182] Uveitis was not seen until 18 to 24 months after the acute outbreak of leptospirosis. Treatment with systemic antibiotics did not seem to affect the uveitis. In this study, serum titers to *L. interrogans* serovar *pomona* often remained high for at least 6 years.[182] In another study, uveitis was seen in 22 eyes of 18 ponies experimentally infected with serovar

pomona. The earliest sign of uveitis was seen at 1 year after inoculation. Anterior uveitis with cataract formation and posterior synechiae were also seen; as were recurrences.[183]

Recently, leptospiral organisms have been identified using PCR[184] or by culture[184–186] in the eyes of horses with ERU. A study in California using a PCR assay for *Leptospira* showed that 30 of 55 eyes (21 of 30 horses) with ERU had detectable *Leptospira* DNA in their aqueous humor.[184] Interestingly, in other studies, treatment with systemic antibiotics did not decrease the inflammation.[187–189] In Western Europe a total of 618 vitreous and/or aqueous samples were taken from the eyes of 501 horses with either active ERU or a history of ERU. Leptospires were isolated from 199 (32.2%) of the samples. Most belonged to serogroup *grippotyphosa,* with the rest in serogroup *australis, sejroe, pomona,* or *javanica*.[185] In contrast, 36 samples of vitreous from 21 normal horses did not grow leptospires.[186] Although leptospires are involved in ERU in many horses with this syndrome, controlling or treating this disease remains a problem. The best means of symptomatic control of ERU at this time appears to be the use of ocular bioerodible cyclosporin A implants.[190] These are placed intravitreally or, more recently, suprachoroidally and were investigated for this drugs ability to control immune-mediated inflammation elsewhere in the body and within the eye. More recently, however, cyclosporine has been shown to be toxic to *L. interrogans* in vitro at the same concentration that is achieved in uveal tissue with a suprachoroidal implant.[190] In one study a leptospiral vaccine in horses with ERU was not recommended.[191] (See also Equine Recurrent Uveitis.)

1284 1285

39.44.5.5 OCULAR MANIFESTATIONS OF EQUINE ADENOVIRUS

Equine adenovirus is a DNA virus that causes bronchopneumonia in foals, especially if they are immunodeficient. Mucopurulent nasal and ocular discharge accompanies the respiratory system disease. Histologically, swelling and necrosis of conjunctival cells with intranuclear inclusions are seen, with accumulation of neutrophils in the lumina and adventitia of uveal blood vessels.[192]

39.44.5.6 OCULAR MANIFESTATIONS OF SALMONELLOSIS IN HORSES

Salmonella species cause one of the more common and serious bacterial enteritides in foals and adult horses. It is often accompanied by septicemia in foals. Anterior uveitis and hypopyon have been seen in animals with salmonellosis, and *Salmonella* species can sometimes be cultured from these eyes.[193]

39.44.5.7 *MORAXELLA* CONJUNCTIVITIS IN HORSES

Two reports have described a *Moraxella* species recovered from several horses in herd outbreaks of conjunctivitis, ocular discharge, and erosions of eyelid epithelium at the canthi.[194,195] The organism was similar but not identical to *M. bovis,* and the disease was reproduced experimentally in horses by instillation of the organism into the conjunctival sac. Huntington et al.[195] described successful treatment of the lesions with chloramphenicol ointment, whereas Hughes and Pugh[194] described the lesions as healing spontaneously.

39.44.5.8

OCULAR MANIFESTATIONS OF EQUINE VIRAL ARTERITIS

Equine viral arteritis is a rare disease caused by an RNA virus classified as Arteriviдae. Most animals are subclinically infected, but ocular and nasal discharges; palpebral, periorbital, limb, or ventral edema; skin rash; pyrexia; rhinitis; leukopenia; abortions; and neonatal death are seen.[196,197] Corneal opacity and apparent photophobia have also been described.[198] The virus characteristically causes a panvasculitis.

39.44.5.9

OCULAR MANIFESTATIONS OF *RHODOCOCCUS (CORYNEBACTERIUM) EQUI* IN HORSES

Rhodococcus equi is a gram-positive coccobacillus that causes bronchopneumonia in young foals. One report of *R. equi* from the eye of a foal with bilateral panophthalmitis and pneumonia can be found.[199] Clinically, the foal had bilateral miosis and hypopyon.

39.44.5.10

OCULAR MANIFESTATIONS OF BORRELIOSIS IN HORSES

Borrelia burgdorferi, the agent of Lyme disease, has been most often described as causing polyarthritis in horses, cows, and dogs. However, one case of apparent ocular disease has been reported in a pony infected with *B. burgdorferi*.[200] Unilateral anterior and posterior uveitis was noted, and spirochetes were found in the anterior chamber. Other clinical signs included arthritis and synovitis of both carpal joints.

39.44.5.11

OCULAR MANIFESTATIONS OF CRYPTOCOCCOSIS AND HISTOPLASMOSIS IN HORSES

Exophthalmia and blindness caused by *Cryptococcus neoformans* have been described in a horse.[201] The frontal sinus and retrobulbar area were involved with a fungal granuloma, but the eye itself was normal. The chorioretinitis seen in other species associated with *C. neoformans* has not been described in the horse. *Cryptococcus albidus* has been cultured from the cornea of a horse with chronic keratitis.[202] Organisms consistent with *Histoplasma* spp. were seen on cytology of a corneal scraping taken from a horse with chronic keratitis.[203] The horse was successfully treated with topical fluconazole.

39.44.5.12

OCULAR MANIFESTATIONS OF EQUINE HERPESVIRUS TYPE 2 (EHV-2)

Equine herpesvirus serotype 2 (EHV-2) has been isolated from eyes in herd outbreaks of keratoconjunctivitis in horses.[204,205] Clinical signs in one outbreak included apparent photophobia, epiphora, corneal neovascularization, corneal color change, and pinpoint ulcerations; eyes healed within 2 weeks.[204] In the other outbreak, conjunctivitis, and multifocal superficial corneal opacities were seen; eyes healed within 2 weeks on topical idoxuridine.[205] Experimental inoculation of EHV-2 intranasally in two ponies pretreated with dexamethasone caused conjunctivitis, as well as lymphadenopathy and coughing.[206] Conjunctiva from both ponies was positive for virus by PCR 6 months after inoculation. EHV-2 can also be isolated from the blood of normal horses,[207] and positive PCR results can be obtained from normal eyes as well as eyes with keratoconjunctivitis, making diagnosis difficult.

Miller et al.[208] confirmed EHV-2 by fluorescent antibody staining after isolating virus from the cornea of a thoroughbred mare with multiple superficial punctate corneal lesions. The keratitis was successfully treated with topical 1% trifluridine ophthalmic solution.*

* Viroptic, Burroughs-Wellcome, Research Triangle Park, NC.

39.44.5.13

OCULAR MANIFESTATIONS OF STRANGLES (*STREPTOCOCCUS EQUI* SUBSP. *EQUI*)

Strangles is a respiratory infection caused by *Streptococcus equi* subsp. *equi* that can have an accompanying ocular discharge.[209] Chorioretinal depigmentation was noted in the nontapetal fundus of several horses in one group clinically diagnosed with strangles. Because these lesions repigmented with time, it was suggested that they were caused by embolism to the choroid during bacteremia.[210] One case of panophthalmitis caused by *S. equi* in a horse has been described.[211] Ten days after a bout of strangles, this horse developed anterior uveitis, which progressed to corneal stromal abscesses and panophthalmitis. *S. equi* was cultured from the eye at enucleation.

39.44.5.14

OCULAR MANIFESTATIONS OF EQUINE HERPESVIRUS TYPE 1

Equine herpesvirus serotype 1 (EHV-1) is a cause of rhinopneumonitis in horses. It has been cultured from cases of superficial punctate keratitis in the horse; the significance of these isolations is unknown.[212]

Six foals were experimentally inoculated intranasally with EHV-1.[213] All developed typical mild signs of upper respiratory infection. One foal developed vision problems 1 month after inoculation. Bilateral chorioretinitis was diagnosed. On necropsy, chorioretinal degeneration with mononuclear cell infiltration in some areas was seen, as well as demyelination of the optic nerve and mononuclear cell infiltrate in parts of the CNS.[213] These findings are not surprising in that EHV-1 causes vasculitis and CNS disease in horses.[214]

39.44.5.15

OCULAR MANIFESTATIONS OF BRUCELLOSIS IN HORSES

Brucella abortus has been suggested as a cause for ERU,[215] although serum agglutination titers for *B. abortus* in normal horses and horses with ERU are similar.[216]

39.44.5.16

OCULAR MANIFESTATIONS OF *MYCOBACTERIUM AVIUM* IN HORSES

A case of anterior uveitis and bilateral chorioretinitis with retinal detachments has been described in a horse from Denmark. Acid-fast organisms were seen in both eyes as well as in numerous other organs. *Mycobacterium avium* was cultured from these organs.[217]

39.44.5.17

INFECTIOUS BOVINE KERATOCONJUNCTIVITIS

JOHN ANGELOS

Infectious bovine keratoconjunctivitis (IBK), or "pinkeye," is the most common ocular disease of cattle and has been identified in cattle populations worldwide. The clinical signs of IBK include corneal ulceration, corneal edema, photophobia, blepharospasm, and lacrimation. In less severely affected animals, recovery with or without permanent corneal scarring occurs. In the most severely affected animals, corneal rupture and lens/iris prolapse may occur, causing permanent blindness. IBK is most common in calves, typically affecting one eye, although both eyes may be affected. Estimates of annual incidence of IBK are 5% of all beef cattle, with more than 50% of herds affected.[218] Epizootics occur, with case-attack rates approaching 90% to 100% of yearling cattle.[219,220] Cattle of all breeds may be affected; however, a higher incidence is reported in Herefords[221] and a lower incidence in Brahmans and cattle with more pigmentation at the ocular margins.[222,223]

39.44.5.17.1

Economic Impact

Cattle with IBK have reduced weight gain that results in economic losses to producers. Postweaning 205-day weights of bulls and heifers with IBK showed losses of 36 and 40 pounds (16 and 18 kg), respectively, over unaffected herdmates.[224] In 1169 pasture-raised calves over a 4-year period, the average weight reduction was 11 pounds (5 kg) for calves with IBK in one eye and 35 pounds (15.75 kg) for calves with IBK in both eyes.[225] A recent study of more than 45,000 health records of weaned calves demonstrated almost 20-pound (9-kg) lighter weaning weights in calves diagnosed with IBK versus healthy calves.[221] The economic losses from reduced weight gains along with treatment-associated expenses account for annual losses in the United States estimated at $150 million in 1976.[226] It is likely that current losses greatly exceed this estimate.

39.44.5.17.2

Etiology and Epidemiology

Moraxella bovis is the only organism for which Koch's postulates have been fulfilled with respect to IBK.[227] However, other viruses and bacteria have also been associated with IBK. Infectious bovine rhinotracheitis (IBR) virus[228,229] and *Mycoplasma* species[230] are probably the most important and likely act as risk factors for IBK by enhancing opportunities for corneal injury[231–233] and increasing ocular and nasal discharge, which may facilitate transmission of *M. bovis*.

Other potentially pathogenic bacteria have been isolated from the eyes of cattle with IBK. In 1966, hemolytic gram-negative cocci were isolated from calves with severe keratitis and corneal ulceration.[234] In Australia, *Neisseria* species were isolated in 24 of 25 outbreaks of IBK; *M. bovis* was identified in only two of these outbreaks.[235] *Neisseria* (*Branhamella*) *catarrhalis* was reported in almost 45% of IBK cases, whereas *M. bovis* was isolated from only 28% of IBK cases.[236] *M. bovis* and *Neisseria* species were also cultured from normal eyes of cattle.[237,238] *M. ovis* and *Neisseria ovis* were reported from cattle in Israel with IBK.[239,240] During summer 2002 in northern California, the majority of bacterial isolates from IBK-affected calves were hemolytic gram-negative cocci.[241] *N. ovis* experimentally inoculated into the eyes of calves did not cause lesions typical of IBK, despite previous corneal irradiation.[242] *M. bovis* has been reported in mule deer with keratoconjunctivitis, although experimental inoculation of *M. bovis* isolates into eyes of mule deer fawns did not result in disease.[243] Recently, hemolytic and cytolytic activity from

culture filtrates of *M. ovis* isolated from cattle with IBK has been described, suggesting a possible role for bacteria other than *M. bovis* in IBK pathogenesis.[244]

In addition to bacterial infection, other risk factors for IBK include flies, solar irradiation, and mechanical trauma from plant awns. *M. bovis* survives up to 3 days on the external surface[245] and 2 days in the gut[246] of face flies *(Musca autumnalis)*. IBK was experimentally induced in cattle that were exposed to face flies that had fed on *M. bovis* cultures.[247] Insecticide-impregnated ear tags or back/face rubbers to reduce fly populations have proved effective in reducing IBK in cattle populations.[248] An association between solar irradiation and IBK is also documented.[249–251] Corneas of calves exposed to ultraviolet (UV) irradiation incur corneal epithelial cell degeneration [252] that predisposes eyes to establishment of *M. bovis* and IBK. An experimental model for IBK has been developed in which calves are exposed once daily for 2 or 3 days to UV irradiation using sunlamps held 24 inches (60 cm) from the corneal surface; after the last exposure, animals are infected by instillation of *M. bovis* into the eye.[253–255] Plant awns, by causing mechanical corneal damage, can predispose eyes to infection with *M. bovis* and IBK.

Hemolytic strains of *M. bovis* are considered pathogenic, whereas nonhemolytic, nonpathogenic *M. bovis* can be isolated from normal cattle,[219,256–258] from cattle exhibiting conjunctivitis,[259] and simultaneously with hemolytic *M. bovis* from cattle with IBK.[258] Outbreaks of IBK typically occur annually during summer months, and such outbreaks may be caused in part by cattle harboring *M. bovis* subclinically.[258,260] Shifting between hemolytic and nonhemolytic phenotypes of *M. bovis* has also been described.[261]

39.44.5.17.3

Pathophysiology of Moraxella bovis

M. bovis produces many hydrolytic enzymes, including C4 esterase, C8 esterase-lipase, C14 lipase, phosphoamidase, phosphatase, leucine and valine aminopeptidases, and gelatinase.[262] Of these, however, only two proteins have been linked to pathogenicity: pili and cytotoxin. Pilin proteins of *M. bovis* are of the *N*-methylphenylalanine type (type 4 pili[263–265]) and enable bacteria to adhere to the corneal epithelium and colonize the surface of the cornea.[266–268]

1286

1287

The *M. bovis* cytotoxin (cytolysin/hemolysin) is a pore-forming protein that is also considered necessary for pathogenesis. Broth supernatants of hemolytic, but not nonhemolytic, strains of *M. bovis* will cause lysis of bovine erythrocytes, neutrophils, lymphoma cells, and corneal epithelial cells in vitro.[269–272] The lytic activity of *M. bovis* cytotoxin occurs through calcium-dependent formation of transmembrane pores in target cell membranes.[273] Ocular lesions induced by a purified hemolytic and cytolytic fraction of *M. bovis* are identical to the ocular lesions observed in naturally occurring IBK; extracts from nonhemolytic *M. bovis* do not result in corneal lesions.[274]

An association between the *M. bovis* cytotoxin and the RTX (***r***epeats in the structural ***t***o***x***in) family of bacterial exoproteins followed the discovery that *M. bovis* cytotoxin induces the formation of pores in target cell membranes.[273] It was subsequently shown that an approximately 110-kilodalton protein in concentrated culture supernatants from cytolytic *M. bovis* cultures could be recognized by a monoclonal antibody to HlyA, an RTX toxin of uropathogenic *Escherichia coli*.[275] The presence of RTX toxins has been reported in a numerous animal pathogens, including *Mannheimia (Pasteurella) haemolytica,* the agent of shipping fever pleuropneumonia in cattle;[276] *Actinobacillus pleuropneumoniae,* an agent of swine

pleuropneumonia;[277] *Pasteurella aerogenes*, an abortifacient in swine and other mammals;[278] and *Actinobacillus equuli,* associated with foal septicemia.[279] Enterohemorrhagic *E. coli* O157:H7 also harbors a plasmid-encoded RTX toxin.[280]

The best-characterized RTX toxin is HlyA of uropathogenic *E. coli*. The gene encoding this toxin is assigned the abbreviation *hlyA* and is contained within a four-gene operon organized 5′-C-A-B-D-3′. The product of the RTX A gene is a structural toxin that must be activated by the RTX C gene product to become hemolytic.[281–283] The activation occurs through fatty acylation of conserved lysine residues.[284,285] After activation the toxin is secreted by membrane transport proteins encoded by the B and D genes and a third protein, TolC.[286,287] The regulation of transcription through the RTX operon in *E. coli* is a complex process and involves the protein RfaH and JUMPStart DNA sequences.[288] As with *E. coli* hemolysin, the *M. bovis* cytotoxin gene *(mbxA)* is contained within an operon that encodes activation and export proteins; this operon is called the *mbx* operon of *M. bovis* and is absent in nonhemolytic *M. bovis*.[289] The *mbx* operon defines a pathogenicity island, and acquisition/loss of *mbx* genes may explain the ability of *M. bovis* to change from the hemolytic to nonhemolytic phenotype.[290]

39.44.5.17.4

Immunity to Moraxella bovis

Secretory IgA is the major immunoglobulin found in normal bovine lacrimal secretions.[291] During experimentally induced IBK, tear IgG1 and IgG2 concentrations increase.[292] Early studies suggested that calves with more severe IBK had higher lacrimal IgA titers to crude *M. bovis* antigen preparations than calves with less severe IBK.[293] A subsequent study identified a predominant tear IgG response to a crude, whole-cell *M. bovis* antigen in calves with naturally occurring IBK and concluded that *M. bovis*—specific antibodies in lacrimal secretions did not prevent IBK in calves.[294] Enzyme-linked immunosorbent assay (ELISA) has been used to quantify nonspecific *M. bovis* antigens in tears and has revealed that IgA titers are higher than IgG titers.[295] A study on a small number of calves then suggested that both lacrimal (secretory IgA) and humoral (IgG) antibodies against *M. bovis* whole-cell antigen conferred resistance against IBK, versus a humoral IgG antibody response alone.[296] It was concluded that serum antibodies against *M. bovis* may account for a reduction in the length and severity of clinical signs associated with IBK. Unfortunately, none of these studies adequately controlled for total antibody isotypes present in serum or ocular secretions. In addition, crude *M. bovis* antigen preparations were used in these assays.

In other diseases associated with RTX toxin—producing pathogens, the protective role of immunity against RTX toxins is not well understood. In one study a *Mannheimia (Pasteurella) haemolytica* leukotoxin subunit vaccine was not protective;[297] however, calves infected with a mutant strain of *M. haemolytica* that secreted inactive leukotoxin had reduced lung lesion scores but similar clinical severity scores as calves receiving wild-type *M. haemolytica*.[298] The introduction of genes encoding the hemolysin (HlyA) into other *E. coli* strains increased virulence,[299] although an HlyA-deficient mutant was still pathogenic.[300] Pigs infected with nonhemolytic *Actinobacillus pleuropneumoniae* developed lung lesions that were similar to lesions in pigs infected with a virulent strain, and it was concluded that the hemolysin of *A. pleuropneumoniae* serotype 2 was not essential for disease.[301] However, another study found that pigs vaccinated with *A. pleuropneumoniae* serotype 1 hemolysin were protected after challenge.[302,303] These studies underscore the fact that immunity to diseases caused by RTX toxin—producing bacteria is complex and may not depend on an antibody response to an RTX toxin alone.

39.44.5.17.5

Experimental Vaccination

Early studies that reported reduced *M. bovis* infection rates and decreased occurrence of IBK after reexposure to *M. bovis* indicated that vaccination against IBK might prevent disease.[250] Subsequent work showed that calves vaccinated intramuscularly with live *M. bovis* had less severe IBK after challenge.[304] Formalin-killed *M. bovis* was also reported to be as effective as live cultures in preventing experimentally induced IBK[305]; under field conditions, however, a formalin-killed autogenous bacterin was not efficacious.[306]

In an effort to identify other candidate *M. bovis* vaccine antigens, researchers began to examine the use of component or subunit vaccines to prevent IBK. In early studies, *M. bovis* pilin antigens were found to protect calves from homologous challenge.[307] Purified *M. bovis* ribosomes were not protective.[308] Bacterin-containing pili plus corneal-degrading enzymes were protective in field trials, and protection was correlated with the corneal-degrading enzyme level in the vaccine.[309] In that study, however, the exact composition of corneal-degrading enzymes was not reported. In a later study, two commercial *M. bovis* pilus-based vaccines were not protective for calves in a heterologous challenge model.[310] Although pilin is immunogenic, there is marked antigenic diversity between different pilin types because of the presence of two structural pilin genes and variability in the amino acid composition of the pilin molecule caused by inversions within pilin genes.[267,268,311,312] Limited antigenic cross-reactivity was reported between heterologous pili,[313,314] and emergence of novel pilus types can precipitate IBK outbreaks.[315] Such antigenic variability is believed to reduce the overall efficacy of pilin-based vaccines. Nevertheless, more recent work has demonstrated conserved epitopes across different pilin types,[316,317] suggesting a possible future role for conserved pilin antigens in vaccines against IBK.

Unlike pili, the *M. bovis* cytotoxin seems to be more conserved across different *M. bovis* strains. IBK-affected cattle were shown to develop systemic immune responses to cytotoxin[318–321] and antihemolysin antibodies to one *M. bovis* strain, neutralized hemolysin from 33 different strains of *M. bovis*.[321] A partly purified cytotoxin vaccine also protected calves against IBK after challenge with heterologous *M. bovis*.[318] These reports suggest a role for a cytotoxin-based vaccine to prevent IBK from multiple *M. bovis* strains, which could therefore be superior to traditional pilus-based vaccines.

1287

1288

Methods to purify partly the *M. bovis* cytotoxin have now been published,[322] and its efficacy in a vaccine to prevent IBK has been demonstrated.[323] The labor-intensive process of preparing native cytotoxin has also led to the investigation of recombinant *M. bovis* cytotoxin vaccines to prevent IBK. In one field trial, calves vaccinated with the recombinant carboxy terminus of *M. bovis* cytotoxin had a lower cumulative proportion of ulcerated eyes compared with saline and adjuvant control calves.[324]

Parenteral routes of vaccination have been tested most often, although aerosol vaccination also has been found to be effective against IBK.[325]

39.44.5.17.6

Treatment and Prevention

IBK prevention hinges on minimizing risk factors for disease, reducing infection of the ocular surface with *M. bovis* through antimicrobial use, and vaccination. To reduce fly populations, insecticide-impregnated

ear tags and topical insecticides with back and face rubbers are employed. Clipping mature grasses before cattle are turned out may also help minimize risks associated with direct mechanical corneal injury from plant awns.

Moraxella bovis is susceptible to numerous approved antimicrobials. These include penicillin administered subconjunctivally,[326] oxytetracycline parenterally or orally (20 mg/kg once or twice followed by 2 g/calf/day for 10 days),[327–329] florfenicol intramuscularly (two 20-mg/kg injections 48 hours apart) or subcutaneously (40 mg/kg once),[330,331] ceftiofur crystalline-free acid subcutaneously (6.6 mg ceftiofur equivalents/kg once) in the posterior aspect of the pinna,[241] and tulathromycin (2.5 mg/kg) subcutaneously.[332]

For vaccination against IBK, most producers use commercially available bacterins. Many different vaccines are available but are not universally effective, as previously discussed. Anecdotal evidence suggests that autogenous vaccines against non—*M. bovis* isolates of gram-negative cocci from IBK-affected eyes may provide an alternative prevention strategy to conventional commercial *M. bovis* vaccines when such vaccines are ineffective.

39.44.5.18 IMMUNE-MEDIATED OCULAR DISEASES

MARY Belle GLAZE

Except for the conjunctiva, the eye has no lymphatic drainage. Access of antigens to potentially reactive lymphoid tissue is also restricted by the avascularity of the cornea and the presence of selective blood-ocular barriers. As unlikely as immunologically mediated abnormalities might seem under these circumstances, immune-related inflammation remains a leading cause of blindness in the horse. Reports of immune-mediated ocular disease in ruminants are rare.

39.44.5.19 Ocular Immunology

The conjunctiva represents an extension of the mucosal immune system. A variety of immune cells can be found in conjunctival tissue, including intraepithelial $CD8^+$ lymphocytes and mast cells, as well as aggregates of $CD4^+$ T-helper (Th) and B lymphocytes, $CD1^+$ dendritic cells and macrophages, and within the substantia propria.[333] The conjunctiva processes ocular surface antigens with the help of regional lymph nodes. Antigen presentation is likely preceded by local tissue damage and release of inflammatory mediators that recruit inflammatory cells to the site. Under the influence of cytokines such as interferon alpha (IFN-α), tumor necrosis factor alpha (TNF-α), interleukin-1 (IL-1), and IL-12 released by local and recruited cells, tissue dendritic cells process and carry host and pathogen molecules to regional lymph nodes to activate $CD4^+$ Th cells. Stimulated lymphocytes migrate back to the conjunctiva (T cells) and lacrimal gland (B cells), where they participate in cell-mediated reactions and local production of IgA and to a lesser degree IgG, respectively.[333–335]

Because the globe itself is without lymphatic drainage, intraocular antigens must be processed at a distant site. These antigens pass into the systemic circulation, preferentially stimulating the spleen as well as the bone marrow and other distant lymphoid organs. After 5 to 7 days, sensitized lymphocytes migrate back to the eye and localize within the uvea and limbal conjunctiva. As with those on the ocular surface, these immunologically competent cells are capable of antibody production and can participate in cell-mediated

reactions. Further exposure to the same antigen can provoke an anamnestic response, endowing the uveal and limbal tissues with behavior comparable to that of a regional lymph node.[336]

The intraocular immune response varies from that of a classic immune reaction, presumably to limit excessive inflammation within the eye. Anterior chamber—associated immune deviation (ACAID) is characterized by preferential stimulation of T suppressor cells that inhibit development of both $CD4^+$ and B cells necessary in delayed-type hypersensitivity reactions and production of complement-fixing isotypes of antibody, respectively.[333,337] Cells in the uvea and corneal endothelium also express Fas ligand (FasL), which limits inflammation through apoptosis of activated leukocytes entering the eye.[333]

Each of the four major types of immunologic reactions occurs within the eye.[338] Type I (immediate) hypersensitivity is usually manifest as conjunctivitis, an acute local inflammatory reaction that follows IgE-mediated release of histamine, proinflammatory cytokines and chemotactic mediators from tissue mast cells, and synthesis of cytokines, leukotrienes, prostaglandins, thromboxane, platelet-activating factor (PAF), and kinins.[339] These mediators of the IgE/mast cell inflammatory pathway increase vascular permeability, constrict smooth muscle, dilate blood vessels, and activate leukocyte chemotaxis and the complement cascade. Allergic reactions of the lids and conjunctiva undoubtedly occur in all domestic species.

Type II (cytotoxic/cytolytic) hypersensitivity is an antibody-mediated cytolytic reaction in which the antigen is a cell surface or basement membrane component. Three basic effector pathways lead to cell destruction: (1) opsonization, with increased efficiency of phagocytic destruction; (2) antibody-dependent cellular cytotoxicity, inducing the release of enzymes capable of destroying cells and digesting basement membranes; and (3) lysis of immunoglobulin-bearing cells.[340] Conjunctival damage resulting from autoantibodies directed against epithelial basement membranes is described in equine ocular pemphigoid.

Type III (immune complex) hypersensitivity may share similar effector mechanisms with those described for cytolytic reactions, but antigen locale accounts for dissimilar disease manifestations in these two pathways. 1288 1289
[339] This immune complex reaction may explain the clinical signs of pemphigus foliaceus[341] and the intraocular inflammation observed in horses after influenza vaccination or contact with infected animals.[342] Antibody-mediated cell destruction has also been implicated in uveitis.[338]

Type IV (cell-mediated/delayed) hypersensitivity is an important factor in contact allergy of the lids and conjunctiva and may also play a role in ocular toxoplasmosis. The tissue destruction associated with herpetic keratoconjunctivitis in the horse has been attributed to a cell-mediated response.[338] Increasing evidence implicates delayed hypersensitivity in the pathogenesis of equine recurrent uveitis.[343,344] The reaction requires an initial antigen exposure that results in sensitization of antigen-specific T lymphocytes. Reintroduction of antigen induces interleukin production, with subsequent T-cell activation, proliferation, and cytokine production. Once activated by cytokines, recruited leukocytes display increased activity to many antigens.[345]

39.44.5.20

ALLERGIC BLEPHAROCONJUNCTIVITIS

In humans, several forms of allergic conjunctivitis are mediated by immunoglobulin E (IgE), and histamine (H_2) receptors have been discovered on the human ocular surface.[346] The ubiquitous presence of H_2

receptors in domestic animals implies a similar distribution[334] and the potential for immediate hypersensitivity reactions of the eyelids and conjunctiva.

Affected animals demonstrate acute swelling of the eyelids and conjunctiva, accompanied by serous ocular discharge, mild conjunctival hyperemia, and pruritus. If the stimulus persists, multiple subconjunctival aggregates of lymphocytes appear as tiny, semitransparent follicles within the conjunctival cul-de-sac. In contrast to bacterial conjunctivitis, crusting and purulent discharge are not typical of allergic conjunctivitis.

Diagnosis of allergic blepharoconjunctivitis is often presumptive, based only on careful and thorough elimination of all other causes of lid and conjunctival swelling. Trauma, orbital inflammation, neoplasia, mechanical irritants, conjunctival parasites, and other infectious agents (both ocular and systemic) should be considered. In support of an allergic etiology, conjunctival cytology may reveal eosinophils in response to mast cell degranulation.

The offending allergen may be difficult to identify. Insect stings and toxic plants (e.g., nettle) are possible causes, as are molds and pollens. Allergic conjunctivitis was described in 17 of 187 cows pastured adjacent to a field of blossoming cotton.[347] A group of Angus-Holstein cattle demonstrated excessive lacrimation and ocular pruritus associated with familial allergic rhinitis. Several inhaled allergens have been incriminated, including capeweed, clover, dock, lucerne, pepper tree, paspalum, wattle, ryegrass, sorrel, and fungal extracts.[348] New feeds and certain drugs (e.g., oxytetracycline, penicillin, sulfas) may produce generalized urticaria, with accompanying eyelid and conjunctival edema.[349] Similar findings have been reported in cattle with milk allergy. Agents directly inducing mast cell degranulation through osmotic or charge interactions include hypertonic saline, nonsteroidal antiinflammatory drugs (NSAIDs), thiopental, opiates, neuromuscular blocking agents, mannitol, radiocontrast agents, polymyxin B, and vancomycin.[350] Occasionally, allergic conjunctivitis may be associated with a topical medication such as neomycin. Clinical signs exacerbate with continued application and diminish when the medication is discontinued.

Ocular signs subside with removal of the offending allergen, but this is often impractical. Individual animals may be treated with a topical ophthalmic corticosteroid preparation such as 0.05% dexamethasone ointment* to hasten resolution of swelling and redness. An agent with antiprostaglandin activity such as oral or parenteral flunixin meglumine† (0.5 mg/kg every 12 hours) may be of benefit in the horse. Signs associated with urticaria respond to a decreasing regimen of oral prednisone or prednisolone, initiated at a dosage of 1 mg/kg once daily in the nonpregnant animal.[351] Single parenteral doses of short-acting corticosteroids, epinephrine, or antihistamines have also been used with reported success in food animals.[348]

39.44.5.21

OCULAR MANIFESTATIONS OF IMMUNE-MEDIATED DERMATOSES

Pemphigus refers to a group of chronic blistering diseases that affect healthy skin and mucous membrane. Although these disorders are of presumed autoimmune origin, their exact pathogenesis is unknown. Direct immunofluorescence reveals intercellular deposition of immunoglobulin G (IgG) and complement within the epidermis. Circulating autoantibodies can be demonstrated in humans.[352] Pemphigus foliaceus and bullous pemphigoid have been described in the horse.[353–356]

Ocular manifestations may include ulceration or crusting of the periocular skin and erosions of the conjunctiva. Chemosis and hyperemia are likely; secondary corneal disease may follow that of the mucous membranes. Diagnosis is based on clinical findings, cytology, histopathology, and positive immunofluorescence of affected skin. See the discussion of immune-mediated dermatologic disorders for therapeutic recommendations and prognosis.

Other immune-mediated diseases, such as systemic lupus erythematosus (SLE), occur infrequently in the horse but can affect the eyelids. In addition to skin lesions, vasculitis may be manifest by hemorrhages in mucous membranes, including the conjunctiva.[353,357]

39.44.5.22 EOSINOPHILIC KERATOCONJUNCTIVITIS

Eosinophilic keratoconjunctivitis is an uncommon disorder of horses characterized clinically by corneal ulceration and plaque formation in one or both eyes.[358–361] Its name is derived from the predominance of eosinophils found in cytologic samples. The specific cause of this disorder is still unknown.

39.44.5.22.1 Clinical Signs

Clinical signs may be unilateral or bilateral and include nonspecific signs of blepharospasm, ocular discharge, and conjunctival hyperemia. Perilimbal corneal ulcers appear as raised, white corneal plaques because of adherent caseous exudates, often accompanied by corneal edema and superficial vascularization.

39.44.5.22.2 Diagnosis

Differential diagnoses include mycotic keratitis, onchocercal keratoconjunctivitis, neoplasia, foreign body granuloma, traumatic keratitis, and calcific degeneration. Definitive diagnosis is based on clinical signs and cytologic findings. Eosinophils and segmented neutrophils predominate in corneal scrapings, with fewer mast cells, plasma cells, and lymphocytes. Light microscopy of corneal tissue reveals coalescing foci of degenerated collagen fibers in the corneal plaques.

39.44.5.22.3 Pathophysiology

The exact cause of the disorder is unknown. The finding of eosinophils in equine ocular surface disease is usually attributed to parasitic infection by *Onchocerca* or *Habronema* species,[362] although neither has been identified in the reported cases to date. One proposed mechanism for eosinophilic keratoconjunctivitis is an allergic or inflammatory response to long-term use of ivermectin as an anthelmintic, triggering the complement cascade and cellular chemotaxis in patients with ocular onchocerciasis.[359] Similarities to vernal keratoconjunctivitis in humans suggest that eosinophil-granule major basic protein may play a significant role in the equine disease, inhibiting corneal epithelial migration and protein synthesis and promoting collagen degeneration.[363] Eosinophil-derived collagenase also has been reported to degrade type I collagen, the predominant collagen in cornea.[358]

1289 1290

39.44.5.22.4 Treatment and Prognosis

Treatment consists of topically applied 0.05% dexamethasone and prophylactic topical antibacterial ointments every 6 hours until clinical signs resolve. Lesions remodel with minimal corneal scarring, but mean duration of treatment in one series of patients was 64 days (range, 45 to 105 days).[359] Use of ophthalmic NSAID preparations may increase the severity of clinical signs of eosinophilic keratoconjunctivitis in horses because of potentiation of leukotrienes, the primary promoter of eosinophilic inflammation.[358] Excision of the corneal plaques by superficial keratectomy appears to enhance healing, attributable to removal of the eosinophil-granule major basic protein.[358,359]

39.44.5.23 IMMUNE-MEDIATED KERATITIS

39.44.5.23.1 Nonulcerative Keratouveitis

Nonulcerative keratouveitis is an uncommon corneal disease in the horse characterized by a pink, vascularized and somewhat localized stromal infiltrate of predominantly lymphocytes near the limbus.[364,365] The overlying epithelium is intact, so fluorescein dye is not retained by the cornea. Accompanying anterior uveitis is typically severe and unremitting, with blepharospasm, epiphora, conjunctival hyperemia, corneal edema, miosis, aqueous flare, and hypopyon. The primary differential diagnosis is a corneal stromal abscess; other considerations include fungal keratitis, eosinophilic keratoconjunctivitis, onchocerciasis, and neoplasia.

The pathogenesis is presumably immune mediated, based on histopathology and response to therapy.[364] Systemic leptospirosis was incriminated etiologically in a 2-year-old thoroughbred filly with a unilateral corneal infiltrate of lymphocytes and macrophages and a choroidal infiltrate of lymphocytes, eosinophils, and basophils that was also positive to IgG and C3.[366] Brooks et al.[364] speculated that autoimmunity against corneal antigens may play a role.

Before beginning therapy, it is essential to rule out stromal abscessation and fungal keratitis, in which the prescribed antiinflammatory regimen would be contraindicated. Treatment consists of a potentially lifelong regimen of a potent topical corticosteroid that will penetrate through intact corneal epithelium (1% prednisolone acetate or 0.1% dexamethasone) every 4 to 6 hours, 1% cyclosporine every 12 hours, and/or an NSAID such as flurbiprofen every 8 hours.[364,367,368] Topical 1% atropine is administered to effect to minimize ciliary spasm and limit synechiae. A systemic NSAID such as flunixin meglumine is administered every 12 to 24 hours. Clinical signs typically recur if medication is discontinued. Prognosis is poor, without expectation of cure. Chronic inflammation may result in phthisis bulbi or unremitting pain that necessitates enucleation.[369]

39.44.5.23.2 Nonulcerative keratitis

Chronic, nonulcerative corneal opacities without signs of overt discomfort or intraocular inflammation have been described.[370,371] In a report of 19 horses age 5 to 11 years diagnosed with nonulcerative keratitis, 11 horses had clinical signs for more than 12 months before referral.[370] The disorder comprises three distinct clinical entities, classified as superficial, midstromal, or endothelial, based on the location of

the corneal pathology. *Superficial* keratitis is characterized by a superficial, white to yellow infiltrate with diffuse, mild to moderate vascularization. *Midstromal* lesions are typically more diffuse, with denser cellular and vascular components. A deep cellular infiltrate with mild corneal vascularization and variable degrees of diffuse corneal edema are typical of *endothelial* keratitis. Intraocular inflammation is not a feature of the disorder, regardless of lesion location. Differential diagnoses include stromal abscess, eosinophilic keratoconjunctivitis, bullous keratopathy, and nonulcerative keratouveitis.

An immune-mediated pathogenesis is theorized, based on histopathologic characteristics and response to therapy. Regardless of lesion depth, histopathology reveals a predominantly lymphocytic-plasmacytic infiltrate, with stromal fibrosis and vascularization. Three of five horses were seropositive for *Leptospira* in one study.[370] Presumably the immune system is reacting to a self-antigen or antigens of a foreign protein or infectious agent within the cornea. Even though infectious agents have not been documented in this particular disorder, immunologic cross-reaction with self-antigens (i.e. molecular mimicry) may occur, as described with leptospiral organisms or their DNA in the equine cornea.[372,373]

Lesions of superficial stromal keratitis can be controlled with long-term topical dexamethasone and/or cyclosporine applied every 12 to 24 hours.[370,371] Lesions in 4 of 11 horses treated by superficial keratectomy and conjunctival grafting resolved without the need for ongoing medication, suggesting that surgical removal of the inciting antigen will stop the inflammatory process. A similar chronic therapeutic regimen is used in midstromal keratitis; Matthews[371] states that topical corticosteroids are less effective than cyclosporine in the deeper stromal disorder. Keratectomy followed by a conjunctival graft was curative in one horse.[370] Response to antiinflammatory agents varies in patients with endothelial keratitis, resulting from differences in pathogenesis. Only two of four horses were controlled with constant topical dexamethasone and cyclosporine in Gilger et al.'s report.[370] In contrast, Matthews[371] described complete resolution of endothelial keratitis with topical 1% dexamethasone applied every 6 hours for 3 to 7 days. Although retention of vision is likely in most cases of nonulcerative keratitis, long-term or even lifelong therapy is required to control the corneal disease.

39.44.5.24 EQUINE RECURRENT UVEITIS (PERIODIC OPHTHALMIA, “MOON BLINDNESS”)

39.44.5.24.1 Definition and Etiology

Equine recurrent uveitis (ERU) is distinguished by a pattern of intraocular inflammation in which recurring episodes of acute uveitis are separated by periods of clinical quiescence. Inflammation of the iris and ciliary body (anterior uveitis or iridocyclitis) predominates in the early stages; repeated episodes damage the cornea, lens, vitreous, retina, and optic nerve. A more insidious form of ERU characterized by persistent, low-grade inflammation occurs in the Appaloosa and draft breeds of horse.

Equine recurrent uveitis is a leading cause of blindness in the horse and mule. Although the exact prevalence is unknown, estimates as high as 10% to 25% have been reported .[374,375] The financial impact on the equine industry is estimated at 100 to 250 million U.S. dollars annually as a result of the effects on performance and the costs of veterinary care.[376] 1290 1291

Despite extensive clinical research, the specific cause of ERU is still unknown. The pathogenesis is immune mediated, and characterization of T-lymphocyte populations in affected horses documents a delayed hypersensitivity reaction as the basic immunologic mechanism underlying the recurrent

inflammatory episodes.[344] Identification of the triggering antigen has proved more elusive, suggesting the disease does not result from the persistence of or repeated exposure to a single antigen, but rather to a variety of circulating antigens or native ocular antigens. *Leptospira interrogans* serovar *pomona* is the most frequently incriminated infectious pathogen,[375] but diversification of T-cell responses to a particular antigen or group of antigens over time may result in evolution of the immune response to encompass endogenous ocular self-antigens.[341,377]

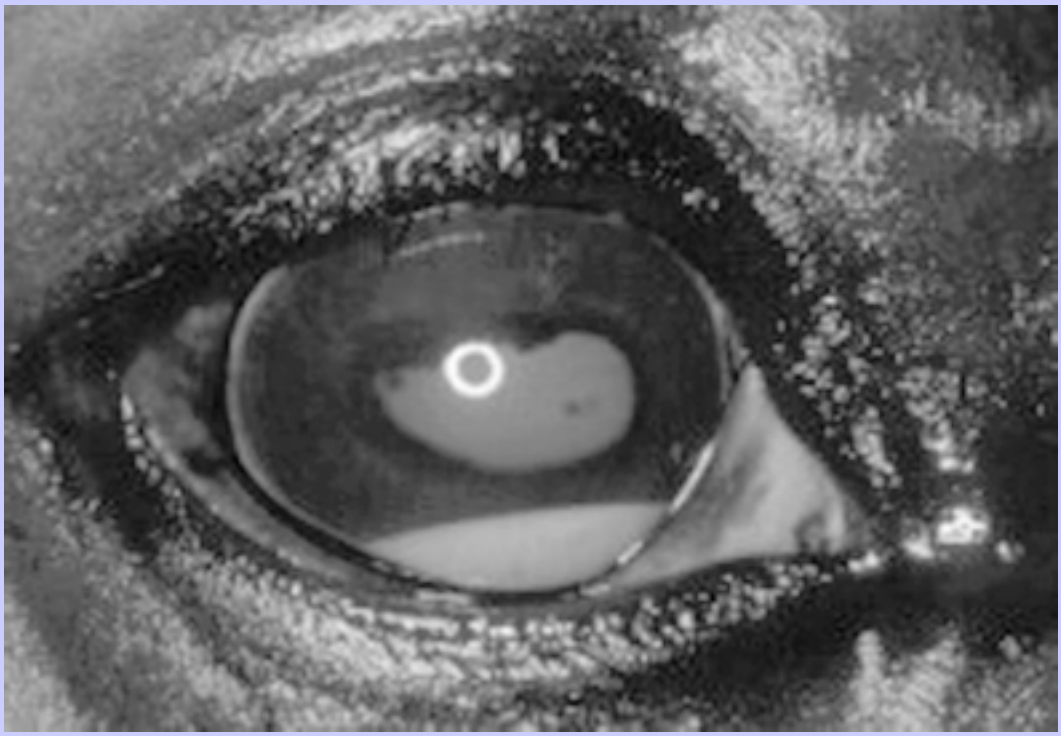
39.44.5.24.2

Clinical Signs

The ocular lesions observed in ERU vary, depending on the severity and duration of the disease.[369,374,376,378,379] ERU can occur at any age, but the initial uveitis episode frequently occurs in horses 4 to 8 years of age. Acute episodes are painful, characterized by blepharospasm and excessive tearing. Affected eyes are often described by owners as “red and/or cloudy” because of changes in the conjunctiva, cornea, anterior chamber, or vitreous. Dilation of subconjunctival vessels near the limbus, termed “ciliary flush,” may intensify the generalized conjunctival hyperemia. As corneal endothelial function decreases, diffuse corneal edema gives the eye a bluish white appearance. The cornea may also exhibit peripheral, circumferential vascularization, cellular precipitates on its inner (endothelial) surface, and linear stromal opacities.

Increased uveal vessel permeability causes the aqueous humor to appear cloudy after influx of plasma proteins (flare), inflammatory cells (hypopyon), erythrocytes (hyphema), or fibrin into the anterior chamber (Fig. 39-25). The iris often appears edematous and lackluster or “muddy.” A change in iris color may be noted in breeds with lightly colored eyes, changing from blue to green in response to uveal edema, vascular congestion, and cellular infiltration. Prostaglandins and other inflammatory mediators cause pupillary constriction, favoring the formation of adhesions between the iris and lens (posterior synechiae) that distort the pupillary shape. Even without adhesions, the inflamed iris responds poorly to mydriatic agents. Intraocular pressure (IOP) is usually decreased because of diminished aqueous production by the inflamed ciliary body, but intermittent IOP elevations can occur.[380] The ciliary body can also deposit cellular exudates within the anterior vitreous, creating an opacity within the pupillary space that may be mistaken for cataract.

Fig. 39-25 Active uveitis characterized by hypopyon, pupillary irregularities secondary to posterior synechiae, melanin adherent to the anterior lens capsule, and a dull tapetal reflection.

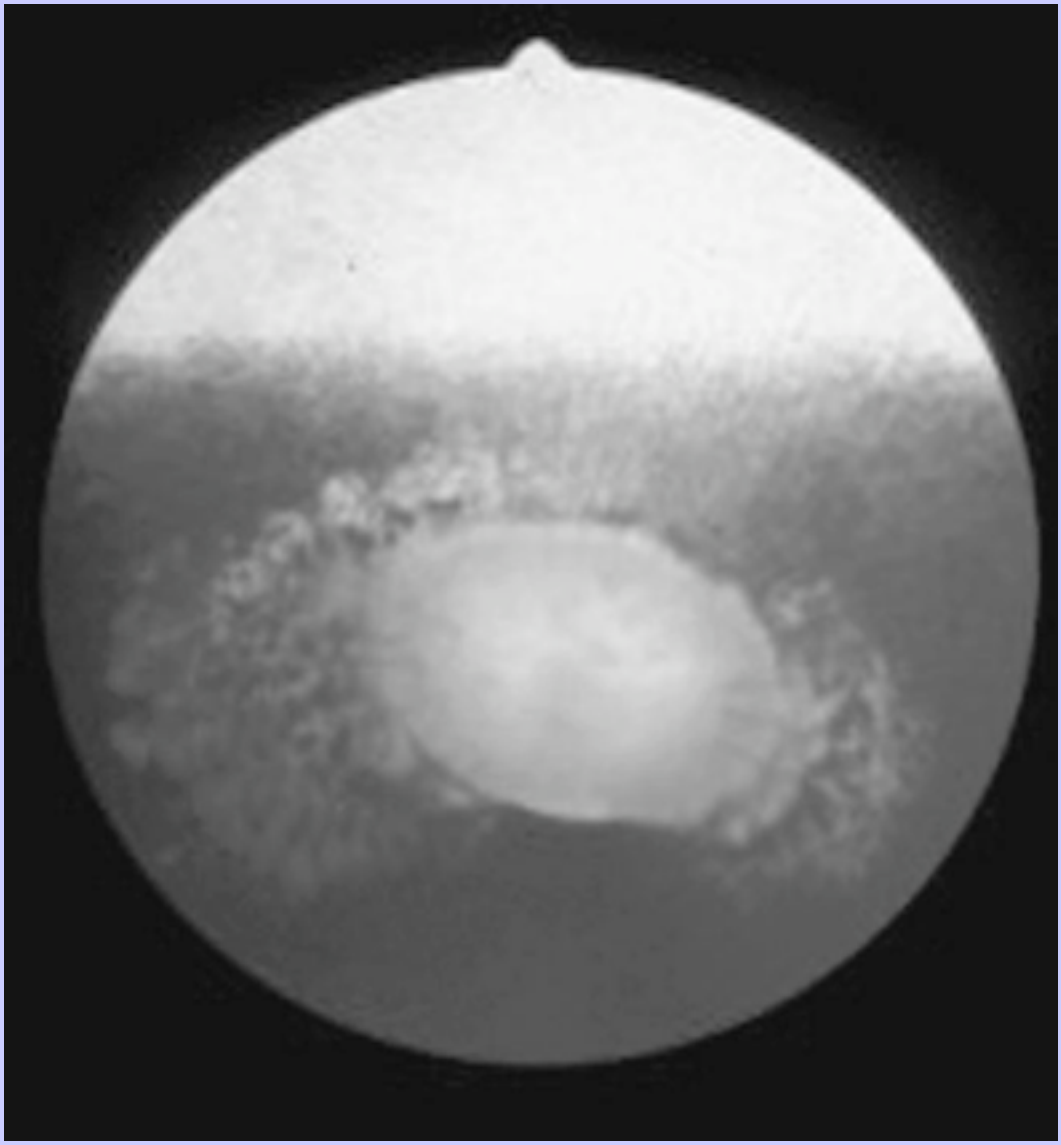


Active chorioretinitis causes dullness and loss of detail in affected tissues. Retinal detachment may follow choroidal exudation. Multifocal depigmented or hyperpigmented foci on either side of the optic disc are the inactive sequelae of chorioretinitis ("chorioretinal scars"), commonly referred to as peripapillary "butterfly" lesions (Fig. 39-26).

Intraocular damage increases each time inflammation recurs. Permanent corneal opacity caused by edema results if the corneal endothelium is severely compromised. Chronic recurrent uveitis is characterized by widespread posterior synechiae, iris depigmentation or hyperpigmentation, and iris atrophy. The anterior chamber may appear shallow if aqueous trapped in the posterior chamber by extensive iris-to-lens adhesions causes the iris to balloon forward (iris bombé). Most lens changes occur weeks or months after uveitis begins. Abnormalities may range from pigment flecks on the anterior lens capsule (Fig. 39-27) to dense cataracts. Lens luxation often follows degeneration of the lens zonules and vitreous. Retinal detachment may also follow vitreous liquefaction or may result from traction by fibrous tissue bands within the vitreous. If retinal degeneration is substantial, the optic disc atrophies (Fig. 39-28). Permanent hypotony is followed by shrinkage of the globe (phthisis bulbi). Conversely, chronic uveitis may result in secondary glaucoma. The combination of these acute and chronic ocular lesions determines the degree of vision loss in the affected animal.

Equine recurrent uveitis may be accompanied by transient and variable inflammation of the pineal gland.[381–384] Similar pineal inflammation has been reported in experimentally induced recurrent uveitis in laboratory animals.

Fig. 39-26 Fundus adjacent to optic disc takes on mottled appearance as a result of pigment migration after previous chorioretinal inflammation in recurrent uveitis. Because of their shape, such lesions are sometimes referred to as “butterfly lesions.”



1291

Fig. 39-27 Prior episodes of anterior uveitis are indicated by pigmented remnants on the anterior lens capsule following adhesions of iris to lens (posterior synechiae). The pupil is pharmacologically dilated.

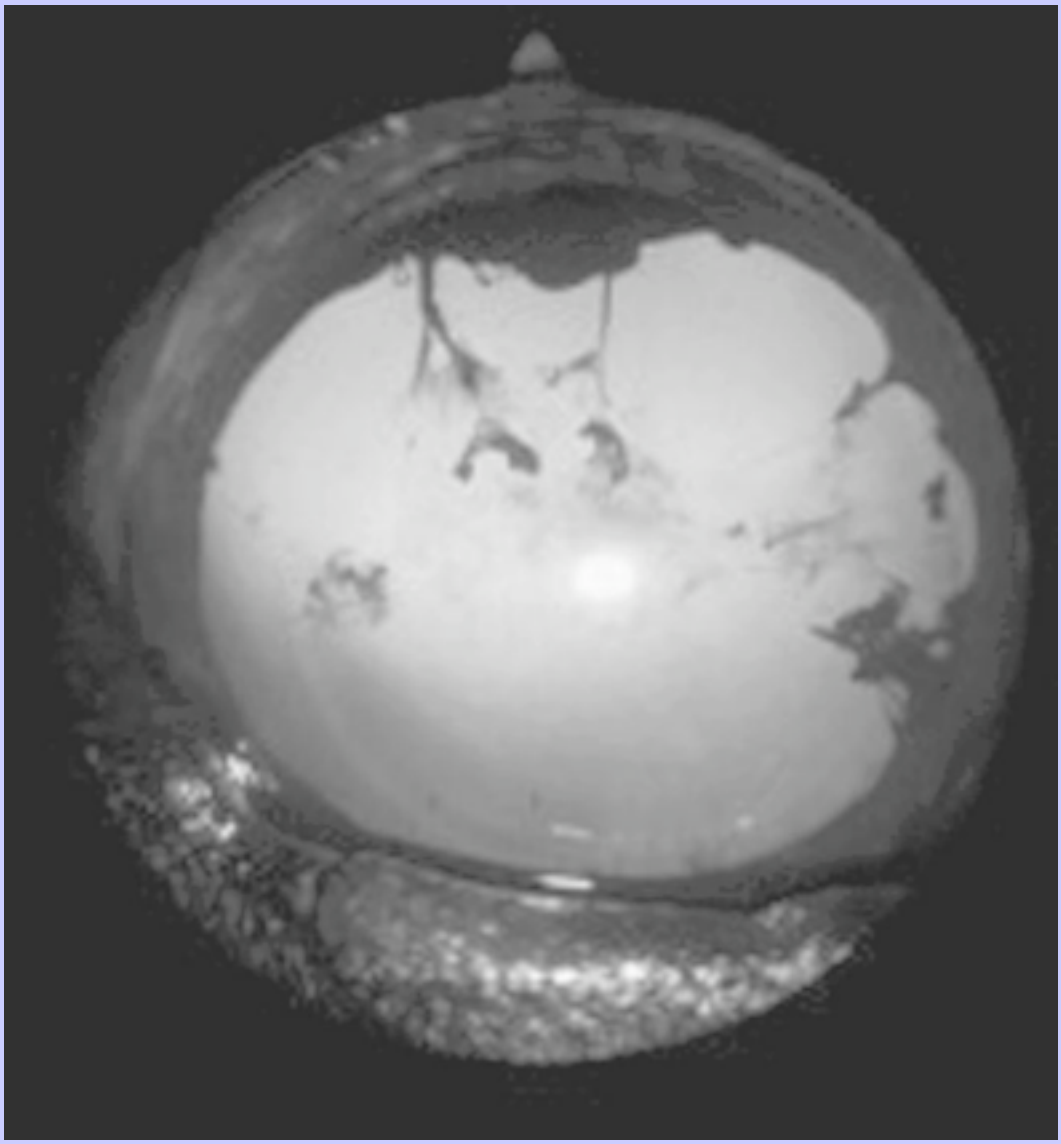


Fig. 39-28 Disc pallor and nontapetal depigmentation accompany a dark-gray pre-retinal exudate in a patient with chronic active recurrent uveitis. This patient had poor vision.

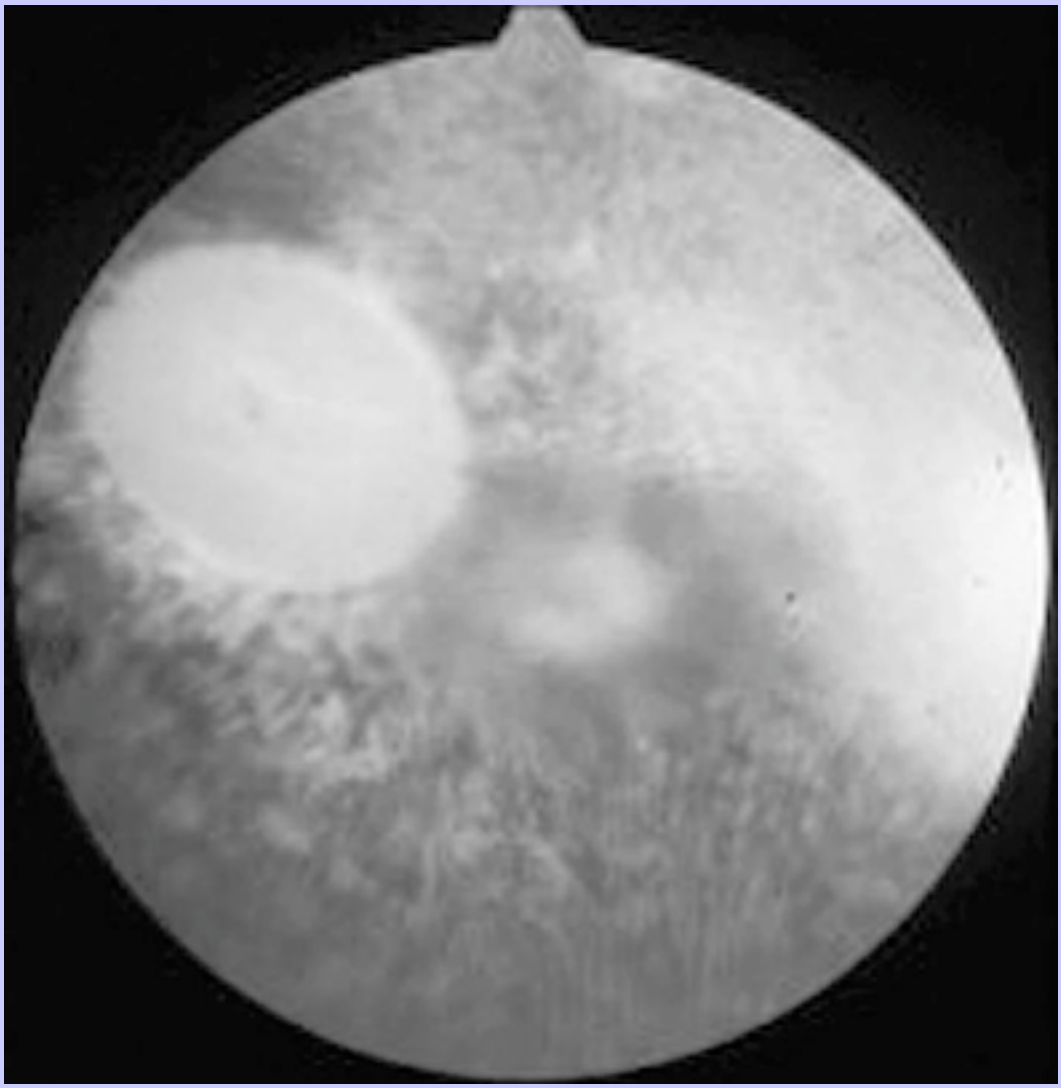

39.44.5.24.3

Diagnosis

Not every case of uveitis in the horse qualifies as ERU. Diagnosis is based on a chronic, recurrent history of intraocular inflammation and the presence of characteristic ocular lesions. In cases in which the history is unknown but recurrent disease is suspected, at least three of the following indicators of previous inflammation should be observed before a presumptive diagnosis of ERU is made: corneal edema or vascularization, synechiae, iris atrophy or color change, lens capsular pigmentation, cataract, lens luxation/subluxation, vitreous opacities or traction bands, retinal detachment, or peripapillary scarring.[374] Other

causes of a red and painful eye that can mimic acute ERU include conjunctivitis, corneal ulceration, corneal stromal abscessation, keratouveitis, and glaucoma.

Serologic testing of paired serum samples for *Leptospira* species or other infectious agents incriminated as causes of equine uveitis (see Table 39-2) may contribute to a diagnosis of ERU, but negative titers neither exclude the diagnosis nor eliminate leptospirosis as a contributing factor to the disease.[385,386] Acute leptospiral infections are characterized by high-titer seroreactivity to at least one serovar by the eighth day;[387] the titer usually falls with time, but seroreactivity may persist for many years. Some authors suggest that a leptospiral titer of 1:400 or higher is of clinical importance, particularly for *Leptospira interrogans* serovar *pomona*.[374] A higher titer in the aqueous than in the serum is indicative of intraocular antibody production and further supports a leptospiral cause for the uveitis.[388] *Onchocerca* microfilariae may be identified in conjunctival biopsies, although detection of live microfilariae does not necessarily indicate a causal relationship.[389,390] Equine leukocyte antigen (ELA) typing may help determine susceptibility to ERU.[391]

Histopathologic lesions of the ciliary body considered pathognomonic for ERU include the presence of a thick, noncellular hyaline membrane adherent to the nonpigmented epithelium (NPE) and the presence of eosinophilic linear cytoplasmic inclusion bodies within the NPE.[392,393] Clusters of lymphocytes and plasma cells also accumulate in the posterior iris, ciliary body, near the ora ciliaris retinae, within the choroid, and near the optic nerve head.[376,394] Dense bundles of fibrils coupled with necrotic cells and mononuclear inflammatory cell infiltrates characterize the changes within the vitreous.[395]

39.44.5.24.4

Pathophysiology

Breed has been established as a risk factor for ERU. In a 1988 retrospective study of more than 16,000 equine patients at Cornell University, researchers determined that the Appaloosa had a significantly higher risk of developing uveitis than did thoroughbreds.[396] A subsequent New York field study substantiated the breed predilection, concluding that the Appaloosa was 8.3 times more likely to develop uveitis than all other breeds combined.[375] Within the Appaloosa breed, those with overall light hair coats and focal dark spots are more likely to develop ERU than horses with a dark, basic coat pattern and a light “blanket” over the rump.[376] Trotters and warmbloods were overrepresented in a report of 130 ERU-affected horses in Germany.[397] Of 669 mares included in a serologic study of leptospirosis, significantly fewer positive titers were found in thoroughbreds and standardbreds.[398]

In humans, an immunogenetic predisposition to certain types of uveitis has been linked to the major histocompatibility complex (MHC), a closely aligned cluster of genes designated the HLA region (for human leukocyte antigen), located on a single chromosome.[399] Similar genetic loci occur in the horse, and the gene products are referred to as *equine leukocyte antigens* (ELAs). Products of these genes are glycoproteins found either on most nucleated cells (class I antigens) or restricted to accessory cells such as monocytes or macrophages (class II antigens). The immunoregulatory role of the MHC is especially important in discriminating self-peptides from those of nonself origin. Recent studies have shown an increased risk of uveitis linked with the MHC class I haplotype ELA-A9 in a group of German warmblood horses.[391] As proposed in studies of human HLA-associated uveitis, cross-reactivity between self-antigens and ELA cell surface peptides could explain an inadvertent immunologic attack on normal cells.[400,401]

1292

1293

Experimental findings in ERU patients indicate that a T-cell—mediated autoimmune mechanism underlies the recurrent episodes of inflammation. T lymphocytes are the predominant cell type to infiltrate the anterior uvea,[343,394] choroid,[402] and vitreous[403] of horses with ERU, and affected horses demonstrate cell-mediated immunity to retinal autoantigens and peptides.[403–405] B lymphocytes have been reported primarily in retinas from horses seroreactive for *L. interrogans* serovar *pomona*, suggesting that *leptospira*-associated ocular inflammation may be a distinct subset of equine uveitis.[406] Equine ciliary body epithelium may play a role in recruitment and activation of leukocytes through expression of a chemotactic cytokine (chemokine),[407] although in the normal ocular microenvironment, ciliary body pigment epithelium suppresses T-cell activation by direct cell contact and the action of unidentified molecular mediators.[408] Analysis of mRNA collected from horses with uveitis demonstrates elevated levels of IL-2 and IFN-γ, indicating a Th1 response in the disease process.[409] In the absence of bacteria or viruses, this Th1 response by $CD4^+$ uveal T-lymphocytes suggests a delayed-type hypersensitivity (DTH) reaction to self-antigens or sequestered antigens in the uveal tract.[344,410] In contrast to the ocular T-lymphocyte population, systemic lymphocytes of ERU-affected horses do not exhibit a Th1 response.[344] The expression of a deviant MHC class II antigen on resident ocular cells (e.g., Müller, retinal pigment epithelial) suggests that aberrant immune regulation may also play a role in ERU.[343,411]

Aqueous and vitreous immunoglobulin levels have been used to characterize immunologic responses within ERU-affected eyes. Using radioimmunoassay, an early study found that aqueous levels of IgG, IgM, and IgA were 50% to 120% greater in diseased eyes than in normal controls, but that the IgG/albumin ratio suggested leakage of protein through an impaired blood-aqueous barrier rather than intraocular antibody synthesis.[412] Subsequent reports support local ocular antibody production but disagree on the dominant immunoglobulin in ERU-affected eyes. Wagner et al.[413] found selectively increased IgA levels in the vitreous of affected horses; Eule et al.[414] reported substantial IgM titers in 79.6% of ERU samples. In contrast to the intraocular immunoglobulins, there are no significant differences in serum immunoglobulin concentrations between healthy and ERU-affected horses.[413,414]

Both exogenous and endogenous antigens have been proposed as stimuli for these basic immunologic responses. One theory suggests that an infectious agent such as *L. interrogans* (or another, perhaps noninfectious, exogenous antigen) causes the initial iridocyclitis. Sensitized immunocompetent cells enter the uvea during this first inflammatory episode, imparting immunologic memory that is specific for the inciting antigen. Subsequent challenge of these cells by the immunogen causes recurrence of the inflammatory reaction.[338,415] However, the premise of an infectious agent that exclusively induces and maintains ERU through a classic anamnestic response does not fully account for the disorder's clinical course and response to therapy.

The role of leptospiral infection in ERU has been studied extensively in recent years. All major serogroups of *L. interrogans* have been identified in the horse and implicated as initiating factors in ERU.[375,386,416–419] In a report of 130 ERU cases in Germany, 58.8% demonstrated positive titers to leptospirosis, an incidence 7 to 10 times higher than the control population.[397] Anti-*Leptospira* antibodies have been found in the serum, tears, aqueous humor, and vitreous of infected horses.[386,417,420–422] Wollanke et al.[422] reported positive serum antibody titers to *Leptospira* serovars in 25% (24/97) of normal-eyed horses and 22% (50/227) of ERU-affected horses, but only the ERU-affected animals had positive antibody titers in the vitreous.[422] Leptospiral organisms have been cultured from the aqueous and vitreous of ERU-affected

horses.[385,386,419,423,424] Horses seropositive to *L. interrogans* serovar *pomona* are reportedly 13.2 times more likely to have signs of uveitis than seronegative horses.[375] Ocular signs during the acute infection are subtle or absent, but overt ocular inflammation develops months to years later.[425–428] Risk factors for equine leptospirosis include rodent and wildlife exposure, proximity to ponds and rivers, a dense equine population on site, and increasing age.[398,429,430]

Although direct *Leptospira*-mediated injury to the eye cannot be ruled out in the pathogenesis of ERU, a growing body of evidence instead links leptospiral infection with autoimmune responses to ocular tissue components. Complement-binding anti-*Leptospira* antibodies capable of cross-reacting with equine corneal tissue and lens have been found in the tear film and aqueous humor of horses with leptospirosis.[420,421,431] These antibodies bind corneal epithelial cells, activating complement and initiating tissue damage, a mechanism replicated in tissue culture.[432] A leptospiral protein epitope that shares antigenic determinants with the equine cornea and lens has been found in bacterial homogenates,[372] and a DNA fragment of several serovars of *L. interrogans* was determined to encode a 90-kilodalton protein that cross-reacts with equine corneal proteins.[373,433] Novel leptospiral lipoproteins, identified as LruA and LruB, stimulate local intraocular IgA and IgG production and also cross-react with equine ciliary body, lens, and retina.[434] Immunohistopathologic examination has also demonstrated leptospiral cross-reactivity with iris pigment epithelium and retina from horses with ERU.[406,435] This antigenic relationship between *Leptospira* species and equine ocular tissues supports the concept of molecular mimicry as a contributing factor in ERU; exposure to exogenous antigens that share molecular structural sequences with equine self-antigens initiates an autoimmune response.[342]

Toxoplasmosis, brucellosis, salmonellosis, streptococcal hypersensitivity, *Escherichia coli, Rhodococcus equi,* borreliosis,[436,437] intestinal strongyles, and onchocerciasis have also been implicated as causes of ERU, with no consistency in culture or serology results in affected horses.[369,375] Viruses suspected of a role in ERU include equine influenza virus, equine herpesvirus (EHV-1, EHV-4),[438] equine arteritis virus, and possibly equine infectious anemia.[369,374,376] More recent studies on vitreous and serum samples from affected horses question the role of *Borrelia burgdorferi,* Borna disease virus, and *Toxoplasma* in ERU.[439,440]

Both humoral and cell-mediated hypersensitivities have been implicated in the lesions of ocular onchocerciasis. Immunoelectrophoretic studies have demonstrated an influx of IgG and complement (C3) into the tears of affected horses in response to larval death.[441] The resulting chemotaxis of mast cells, eosinophils, and lymphocytes perpetuates the inflammatory response and facilitates destruction of the parasite. Human patients with ocular onchocerciasis demonstrate conjunctival infiltration by $CD3^+$ T lymphocytes and increased expression of class II MHC antigens in conjunctiva and iris,[442] as well as deficiencies in suppressor T-cell function that may interfere with the normal regulation of antibody function.[443]

In addition to the role of infectious agents in the pathogenesis of ERU, autoimmunity may occur when a normally sequestered component is exposed to lymphoid cells or when the antigenicity of a component increases as a result of a structural alteration.[444] Several endogenous ocular proteins, including retinal soluble antigen (S-antigen, or S-Ag), interphotoreceptor retinoid-binding protein (IRBP), and uveal melanin-associated proteins are known to induce uveitis in various animal models.[445–448] Clinical studies

also implicate these potent autoantigens in the pathogenesis of some forms of human uveitis.[449–451] An autoimmune phenomenon in response to damaged uveal tissue has been proposed in the pathogenesis of ERU.[452] The isolation of S-antigen in the horse and the subsequent finding of anti-S antibodies in the aqueous humor and vitreous of horses with uveitis support the theory that this species is similarly capable of local production of antibodies to normally sequestered autoantigens.[403–405,453] Experimental uveitis with features similar to spontaneous ERU has also been induced in horses after injection of IRBP in complete Freund's adjuvant.[402] Autoantibodies to S-Ag and IRBP were found in 72% of vitreous specimens from horses with uveitis.[403] A more recent equine study concluded retinal S-Ag is a weaker autoantigen than IRBP; T and B cells were activated after immunization with S-Ag, but only one of five horses developed uveitis or demonstrated inflammatory cell infiltration of the uveal tract.[454] Because the retina and NPE of the ciliary body originate from neuroectoderm, it is even possible that ciliary body damage may release an S-like antigen or another uveitogenic substance.[455] Evidence suggests that response to S antigen is predominantly T-cell dependent.[456]

Verma et al.[434] proposed a link between leptospiral cross-reactivity and the release of other ocular autoantigens, based on strong IgG and IgA responses to LruA and LruB lipoproteins in uveitic eyes but not in companion sera. The early phase of ERU may involve production of non-complement-fixing antibody and non-DTH T lymphocytes specific for LruA and LruB. The antibodies and cells react with the leptospiral lipoproteins, initiating a process that ultimately liberates IRBP and other ocular autoantigens.

The concept of “epitope spreading” has been offered as an explanation for the relapsing character of ERU.[457] The theory proposes that after destruction of an initial target, the immune response spreads from the first autoantigenic determinant to others not previously recognized by the immune system.[458,459] Active uveitis subsides as regulatory cells suppress the inflammation, recurring as the immune response shifts to an epitope of the same autoantigen (intramolecular spreading) or a completely different autoantigen (intermolecular spreading). A recent 22-month study of peripheral T-cell reactions in eight horses with spontaneous ERU demonstrated intramolecular shifts to different S-Ag—derived (6/8) or IRBP-derived (5/8) epitopes and intermolecular shifts in all horses, spreading from IRBP-derived to S-Ag—derived peptides (5/8), or vice versa (3/8).[457] A shift of the immune reaction could be correlated to new uveitic episodes in 10 of 14 relapses that occurred during the observation period. The confounding factor in this theory is the shifts in immune response observed during quiescent stages, perhaps to minor uveitogenic epitopes that fail to result in overt inflammation, or as part of an unknown regulatory or protective function of these T-cell clones.

Regardless of etiology, the ocular inflammatory process may attract other reactive lymphocytes to the eye. During primary uveitis, only 10% of the ocular immunoglobulin-secreting cells are specific for the inciting antigen. The remaining cells produce antibodies against immunogens that may not have entered the eye, but with which the host had previous contact. As a consequence, the eye may develop recurrent inflammation after systemic exposure to any one of multiple antigens. It is therefore conceivable that subsequent episodes of uveitis may differ etiologically, creating a perplexing clinical picture.[460]

39.44.5.24.5 Treatment

39.44.5.24.5.1 ACTIVE INFLAMMATION

Reduction of intraocular inflammation is the primary therapeutic objective in acute uveitis. Preservation of vision depends on successful management at this stage, when sight-threatening sequelae are minimal. If a specific cause for the uveitis is identified, it is also targeted pharmacologically. In most cases, symptomatic therapy combines corticosteroids, NSAIDs, and mydriatic/cycloplegic agents. Nonspecific suppression of T-lymphocyte activation with cyclosporine implants[461] and surgical removal of T cells and potentially organisms from the eye by core vitrectomy[462] are recent innovations aimed at preventing recurrence of disease.

No therapy is indicated in nonpainful eyes with lesions of chronic end-stage uveitis. Those eyes that remain painful or do not respond to therapy are candidates for enucleation or evisceration, followed by silicone prosthesis implantation in the orbit or sclera, respectively.

39.44.5.24.5.2 Corticosteroids

The severity of the uveitis dictates the routes and frequency of corticosteroid administration. Although topical therapy is most often used, efficacy is limited by the agents' relatively short contact time with the eye. Therefore, topical corticosteroids must be applied three or four times daily, even in eyes with mild clinical signs. In more severe uveitis, topical preparations should be applied every 2 to 4 hours or combined with other routes of therapy. A subpalpebral lavage system should be considered when such frequent application is indicated (see under Bacterial Keratitis in Horses).

Either ophthalmic solution or ophthalmic ointment is acceptable for topical use in the horse. Prednisolone acetate* has excellent intraocular penetration and is considered the drug of choice. Potent dexamethasone preparations (Maxidex)† are also effective. In general, therapy should be continued for at least 2 weeks after clinical signs have resolved. Ideally, that assessment includes an objective IOP measurement to ensure resolution of ciliary body inflammation and dysfunction.

The subconjunctival injection of a repository corticosteroid preparation is an alternative or supplement to frequent topical therapy. Triamcinolone acetonide‡ is effective for 1 to 3 weeks when injected in a 0.5- to 1.0-mL volume (20 to 40 mg) beneath the superior bulbar conjunctiva. Subconjunctival methylprednisolone acetate§ has comparable antiinflammatory effect but is more likely to cause granuloma formation at the injection site. Duration of effect of either drug depends on the severity of the uveitis. Nonocular use of either drug has been linked to equine laminitis.

Evaluation of inflamed eyes should always include topical application of fluorescein dye to rule out ulcerative keratitis. This precaution is especially critical when considering the use of subconjunctival corticosteroids that deliver prolonged and irreversible effects. Topical and subconjunctival corticosteroids are contraindicated in the presence of corneal ulcers because they delay healing, potentiate the destructive effects of endogenous and microbial enzymes, and predispose the cornea to secondary infection.

39.44.5.24.5.3

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Parenteral corticosteroids may be used when topical and subconjunctival agents are ineffective in controlling inflammation, but NSAIDs are usually preferred in such cases. Use of these antiprostaglandin agents counteracts an important mediator of intraocular inflammation, minimizing the role of parenteral steroids in uveitis therapy and the attendant risk of laminitis. Flunixin meglumine (Banamine) is the NSAID of choice for the eye, administered at a dose of 0.5mg/kg intravenously or intramuscularly twice daily for 5 days, then 0.25 to 0.5mg/kg orally once or twice daily. Oral phenylbutazone* at 4.4 mg/kg twice daily can be used in cases of mild uveitis or in animals requiring chronic low-dose oral prophylaxis for recurrent disease. Dosage requirements for aspirin make it less practical in acute cases, but prolonged oral administration of 15 mg/kg twice daily has been used to avert relapses. Frequency of NSAID administration should be reduced as clinical response occurs, because antiprostaglandins have been linked to gastrointestinal ulceration and renal dysfunction with high doses or chronic use.

1294 1295

Topical ophthalmic NSAIDs are generally more costly than and not as potent as corticosteroids if used alone. However, an additive antiinflammatory effect can be seen when topical NSAIDs are used in conjunction with topical corticosteroids in horses with acute or resistant uveitis. Although generally considered a safe alternative to topical corticosteroids in the presence of corneal ulceration, topical NSAIDs have been implicated in the development of melting corneal ulcers in humans. Available generic solutions include 0.03% flurbiprofen sodium† and 0.1% diclofenac sodium.‡ Dosage frequency is empirical, with intervals ranging from 6 to 12 hours.

39.44.5.24.5.4

MYDRIATIC/CYCLOPLEGIC AGENTS

A parasympatholytic mydriatic/cycloplegic agent must be used if equine uveitis is to be managed successfully. By dilating the pupil and decreasing iris-to-lens contact, the chance of posterior synechia formation—and secondary glaucoma—is reduced. An adequately dilated pupil may also promote vision during the acute episode. Ciliary spasm is relieved, making the horse more comfortable, and the iridociliary vessels return to a more normal state of permeability, with normalization of aqueous humor constituents.

Topical application of 1% atropine solution or ointment is indicated two to four times daily until the pupil dilates. The ultimate goal is to maintain mydriasis with the least frequent application possible, keeping in mind the resistance of the inflamed iris and ciliary body to the effects of atropine. Horses on an intensive parasympatholytic regimen should be strictly monitored for signs of reduced gut motility and colic because systemic effects occur with frequent topical atropine administration.[463] Pupillary dilation may persist for 4 weeks or more after cessation of therapy.

If mydriasis is slow or incomplete, 10% phenylephrine hydrochloride solution may be used topically in conjunction with atropine.[464] Although a study in the horse suggests that phenylephrine is ineffective when combined with a parasympatholytic agent, investigators did not rule out a possible benefit if dosage or duration of therapy was increased.[465] However, frequently applied phenylephrine has been associated with the development of corneal ulcers, corneal endothelial toxicity with secondary corneal edema, and increased uveal exudation, so response to the drug should be carefully monitored.

39.44.5.24.5.5

ANTIBIOTICS

Because current evidence suggests an immune rather than an infectious basis for recurrent uveitis, antibiotics have assumed a secondary role in ERU management. Topical antibiotic preparations may discourage opportunistic bacteria during intensive corticosteroid therapy; however, few will cross the intact cornea and reach therapeutic levels in the anterior chamber or uveal tract. In horses with positive leptospiral titers in serum or ocular fluids, systemic antibacterial therapy with oral doxycycline (10 to 20 mg/kg twice daily for 4 weeks) may minimize recurrences of uveitis.[466]

39.44.5.24.5.6

OTHER THERAPIES

If leptospiral infection has been well documented in a group of horses with uveitis, periodic vaccination against the disease may be considered. However, although vaccination significantly increased the interval to recurrence (median, 126 days) compared with nonvaccinated controls (median, 86 days), the practice failed to slow the progression of disease in a group of 41 ERU-affected horses.[467] Currently, no commercial bacterin is approved for use in the horse.

An intracameral injection (25 µg/0.1 mL) of tissue plaminogen activator (tPA) can be used to accelerate fibrinolysis and clear hypopyon in the anterior chamber of horses with severe uveitis. However, tPA should be avoided in eyes with evidence of hemorrhage in the previous 48 hours.

The precise role of *Onchocerca* species in the pathogenesis of ERU is not yet determined, and considerable controversy exists regarding the necessity or benefit of microfilaricidal therapy in cases of ocular onchocerciasis (see later under Ocular Parasites).

Acupuncture and homeopathic remedies such as poultices of chamomile and oral methylsulfonylmethane (MSM) have been used in the treatment of ERU, but efficacy of these unconventional modalities is unknown.

39.44.5.24.6

Prevention of Disease Recurrence

39.44.5.24.6.1

CYCLOSPORINE

Cyclosporin A (CsA) is a noncytotoxic, immunosuppressive drug that blocks the transcription of IL-2 and decreases T-cell responsiveness during the initiation of inflammation.[468,469] These properties could block the nonspecific activation of T cells in recurrent episodes of ERU. With its poor inherent antiinflammatory properties, cyclosporine is likely to be more effective in preventing recurrences than treating active inflammation. Unfortunately, topical application of cyclosporine fails to achieve effective

intraocular levels in horses and other species.[470] However, reports of sustained intraocular levels of CsA in ocular tissues[471,472] and resolution of clinical signs in experimental uveitis after implantation of a CsA-impregnated device into the vitreous of rabbit eyes[473] set the stage for implantation of a similar device into the anterior vitreous of horses with experimental uveitis. The CsA-containing implant significantly decreased the duration and severity of inflammation, cellular infiltration, tissue destruction, protein concentrations, and the level of transcription of proinflammatory cytokines in the experimental group.[461] The intravitreal device also prevented recurrences in 81% of horses with spontaneous ERU, but overall success was limited by complications from intraocular hemorrhage, cataract progression, and retinal detachment.[474] Because of significant risk of postoperative complications in the face of concurrent inflammation, a horse with active uveitis is not a suitable candidate for cyclosporine implantation until the inflammation is adequately controlled by conventional means.[376] Intravitreal delivery devices containing other immunosuppressive agents such as tacrolimus are also effective in suppressing inflammation after intravitreal implantation in rabbits with experimental uveitis.[475]

To minimize ocular morbidity related to implantation, ongoing studies of cyclosporine have focused on development and evaluation of a deep scleral delivery device.[476] Superficial episcleral implantation failed to achieve substantial intraocular levels of CsA or control inflammatory episodes in ERU-affected horses. Therefore, effects of a bioerodible implant infused with CsA and inserted into the suprachoroidal space beneath a partial-thickness scleral flap 1 cm posterior to the dorsolateral limbus were studied. Initial reports of the suprachoroidal device are encouraging. High concentrations of CsA were achieved in the equine ciliary body, choroid, retina, and optic nerve. In horses with severe ERU, only 15% of eyes were blind a mean of 14.2 months after implantation. In contrast, 90% of patients with severe ERU treated conventionally are blind within 1 year.[376] In vitro studies of CsA also documented a direct inhibitory effect on *Leptospira* growth at concentrations achievable within the uveal tissues after deep scleral implantation. Duration of CsA delivery with current devices is approximately 24 months.

1295 1296

39.44.5.24.6.2

CORE VITRECTOMY

Pars plana vitrectomy has been used to remove fibrin, inflammatory cells, and debris trapped in the vitreous; improve vision; and delay progression of clinical signs in affected horses.[462,477,478] Proponents theorize that removal of T cells or infectious organisms such as *Leptospira* may reduce adverse interactions between the vitreous and the uveal tract, thereby reducing the recurrence of ERU. The technique appears more beneficial in European warmbloods with ERU than in Appaloosas with ERU in the United States. In one German study, recurrence of ERU was prevented in 85% (29/34) of treated eyes followed for 5 months to 5 years, but 45% of horses developed significant cataract formation.[462] A study of vitrectomy performed in the United States was also complicated by postoperative cataract formation and progressive loss of vision, despite some decrease in recurrence of uveitis.[479] More recent reports of vitrectomy performed on more than 1200 eyes at the University of Munich described no further recurrences of ERU in 98% of patients.[480] Cataract formation and retinal detachment were reportedly rare in this group of animals. Investigators explained their success on the basis of improved patient selection and surgical expertise.

39.44.5.24.7 Prognosis

The long-term prognosis for vision in horses with recurrent uveitis is poor, although statistics of actual rates of vision loss are limited. Dwyer's 11-year study of ERU-affected horses reported that 56% of the 160 study animals experienced blindness in one or both eyes.[376] Appaloosas and *Leptospira*-seropositive horses were at increased risk for blindness over the course of the study. All seropositive Appaloosas (100%) lost vision in at least one eye; 50% were completely blind. Of seronegative Appaloosas, 72% lost vision in one or both eyes; 29% were totally blind. Seropositive horses of other breeds lost vision in one or both eyes 51% of the time, with total blindness in only 17%. Seronegative, non-Appaloosas had the best prognosis, with 34% losing vision in one or both eyes and total blindness in only 6%.

39.44.5.25 BOVINE-SPECIFIC OPHTHALMIA

A recurrent uveitis of cattle has been described and compared to that of the horse.[481,482] As with ERU, its definitive etiology is unknown, although a viral infection was originally suggested. Clinical signs include conjunctival hyperemia, corneal edema and vascularization, inflammatory cells and hemorrhage within the anterior chamber and uveal tract, and retinal and choroidal edema and hemorrhage. The disorder is uncommon and does not share the notoriety of its equine counterpart. Therapy is directed at reducing inflammation, as described for the horse.

39.44.5.26 OCULAR PARASITES

ROBERT ENGLISH

MARK NASISSE

Parasites are an often overlooked cause of ocular disease in large animals. Many ocular parasitic diseases can threaten vision and can reduce the economic value of the animal through decreased function, decreased production, or both. The mechanisms by which parasites damage ocular tissues are extremely varied and range from direct tissue effects of aberrant parasite migration to complex immunopathologic responses to parasitic antigens. This section reviews the major ocular parasites of large animals, with reference to the ocular tissue of primary importance. Parasitic eyelid diseases are discussed in Chapter 40.

39.44.5.27 CORNEAL AND CONJUNCTIVAL PARASITISM

39.44.5.27.1 Ocular Onchocerciasis

Ocular disease caused by *Onchocerca cervicalis* is the result of aberrant migration of noninfective microfilariae into the palpebral, conjunctival, and corneal tissues.[483] The larvae do not appear to have a predilection for ocular tissues; rather, the eye is involved merely as part of a generalized subcutaneous migration. Approximately 50% of horses with cutaneous onchocerciasis will have ocular involvement.[484]

The pathogenesis of ocular onchocerciasis remains unclear. In humans, keratoconjunctivitis and uveitis associated with local presence of *Onchocerca volvulus* microfilariae occur only after the microfilariae die. Because *Onchocerca* microfilariae are typically found in equine ocular tissues without evidence of

inflammation, a similar mechanism is probably involved. Therefore, some change in the parasite and/or in the host's immune response likely occurs to incite an inflammatory response.

Ocular onchocerciasis occurs mostly in adult horses. The older the host, the greater is the exposure to the vector and the parasite, and presumably the greater the potential for ocular migration of microfilariae. Furthermore, increased immune sensitivity may occur with increased exposure to dead microfilariae.

39.44.5.27.2

Clinical Signs

Conjunctivitis and keratoconjunctivitis concentrated at the temporal limbus are the most common manifestations of ocular onchocerciasis. Acutely, chemosis and hyperemia of the conjunctiva occur, accompanied by increased lacrimation and blepharospasm. Small, raised, white nodules (0.5 to 2 mm in diameter) in the limbal conjunctiva and similar-sized punctate, subepithelial corneal opacities are often present. Corneal lesions are often wedged shaped, with the base of the triangle at the limbus, and are characterized by varying degrees of superficial and deep neovascularization and cellular stromal infiltrates. Untreated, the lesions progressively enlarge, although the rate of progression and the severity of the disease vary. With chronicity, patches of depigmentation (vitiligo) occur in the perilimbal bulbar conjunctiva. Recurrent episodes of keratoconjunctivitis are common.

Migration and subsequent death of microfilariae in the uveal tract result in uveal inflammation. Both the anterior and the posterior uveal tract may be involved. The clinical signs of *Onchocerca* uveitis include apparent photophobia, epiphora, miosis, aqueous flare, inflammatory cells in the anterior chamber, and globe hypotonicity. However, these signs are not specific for onchocerciasis, and other etiologies must be considered (see Table 39-2).

1296

1297

Chorioretinitis reportedly is a common manifestation of posterior segment involvement. Active lesions are recognized ophthalmoscopically by hyporeflective areas, representing chorioretinal edema and inflammatory exudates, usually observed around the optic papilla in a “butterfly-shaped” pattern.[485] However, aqueous and vitreous opacification often precludes accurate assessment of the fundus.

39.44.5.27.3

Diagnosis

Characteristic clinical signs are highly suggestive of *Onchocerca* keratoconjunctivitis, but definitive diagnosis requires corneal or conjunctival biopsy. Conjunctival biopsy may be collected after topical anesthesia, whereas general anesthesia is necessary for partial-thickness lamellar keratectomies to obtain corneal biopsies. A single, 3- to 5-mm biopsy is divided into two samples. One sample is placed on a slide with physiologic saline, minced, and warmed to 37° C (98.6° F) to stimulate larvae movement and therefore enhance their detection. Slides are examined repeatedly over the next hour for migrating microfilariae. The organisms are 200 to 240 mm long and 4 to 5 mm in diameter, with a short, unsheathed tail. The other half of the biopsy specimen is placed in 10% buffered neutral formalin for histopathologic examination.

The presence of microfilariae in ocular tissue does not substantiate a diagnosis of *Onchocerca* keratoconjunctivitis unless evidence of a host inflammatory response exists. The cytologic response is usually pleomorphic, with neutrophils, lymphocytes, plasma cells, and eosinophils present. Varying degrees of neovascularization, pigmentation, lamellar disorganization, collagen degeneration, and calcification are present in the cornea. The overlying epithelium becomes thickened and keratinized. The presence of eosinophils in corneal and conjunctival scrapings is suggestive of a parasite etiology; however,

Onchocerca microfilariae are rarely found. Definitive diagnosis of *Onchocerca* as the cause of uveitis is rarely possible.

The differential diagnosis for equine keratoconjunctivitis also includes squamous cell carcinoma, habronemiasis, and mycotic infections. Because horses with ocular *Onchocerca* have a generalized larval migration, they may also have dermatitis, especially of the ventral thorax.

39.44.5.27.4

Treatment

In humans chronically infected with *O. volvulus,* systemic ivermectin therapy decreases ocular microfilaria burden and improves associated ocular disease. In horses, however, microfilaricide therapy has been associated with increased ocular inflammation. Therefore, treatment is directed at first controlling the inflammatory reaction and then eliminating the parasite.[486,487] Corticosteroids are the mainstay of this initial antiinflammatory treatment and may be given topically, subconjunctivally, or systemically, depending on the severity of the inflammation, the extent of ocular and dermal involvement, and the temperament of the horse.

Because of superior solubility, prednisolone acetate[*] and dexamethasone alcohols[†] are the preferred topical corticosteroid preparations. Mild lesions without concurrent uveitis are treated four to six times daily. When keratoconjunctivitis is severe or when uveitis is present, hourly application may be indicated. Subconjunctival corticosteroids are also beneficial but must be used with caution if corneal ulceration exists or is possible. Therapy is tapered as the inflammation is controlled.

Systemic corticosteroids are indicated for severe uveitis, with concurrent *Onchocerca* dermatitis, and before larvicidal therapy. Prednisolone, at an initial dose of 0.5 to 1 mg/kg daily for 5 to 7 days, is tapered as the inflammation decreases. Refractory cases have been treated for extended periods with 0.25 mg/kg prednisone every other day.[488] The antiprostaglandin activity of NSAIDs such as phenylbutazone and flunixin meglumine is also beneficial, especially when corneal ulceration prohibits the topical use of corticosteroids.

Elimination of the microfilariae is recommended once inflammation is controlled (see Chapter 40). The use of topical antibiotics is also recommended to prevent bacterial infection when corneal or conjunctival epithelial ulceration is present. With uveal involvement, topical mydriatic/cycloplegic agents such as atropine are indicated to relieve ciliary spasm and reduce the risk of posterior synechia formation.

* Pred-Forte, Allergan Pharmaceuticals, Irvine, CA.

† Maxitrol, Alcon Laboratories, Fort Worth, TX.

39.44.5.27.5

Ocular Habronemiasis

Equine ocular habronemiasis occurs when larvae from *Habronema muscae, Habronema microstoma,* or *Draschia megastoma* are deposited on ocular tissues. Flies serving as intermediate hosts for *Habronema* are attracted to moist areas of the body, including the conjunctiva, for feeding; ocular discharge and periocular wounds provide additional sites. As the flies feed, *Habronema* larvae are deposited on the surface of ocular tissues, migrate into the tissues, and produce a local granulomatous inflammatory reaction. Equine habronemiasis occurs worldwide.

39.44.5.27.6

Clinical Signs

Ocular lesions typically consist of raised, proliferative, nonhealing wounds present at the medial canthus. The lesions are friable and pruritic and bleed easily. Lesions often contain small (1 to 2 mm), yellow, caseated nodules ("sulfur granules"). Fistulous tracts and subdermal nodules may develop below the medial canthus. Corneal neovascularization, edema, and ulceration can occur as a result of altered lid function and irritation to the cornea from contact with the rough, irregular surface of the lesion. Corneal involvement increases the degree of ocular pain and blepharospasm.

Habronemiasis lesions are typically seasonal, occurring in the warm summer months when the fly population increases. Certain horses appear to be predisposed to developing cutaneous and ocular habronemiasis, and recurrence may be seen in these animals each summer.

39.44.5.27.7

Diagnosis

Demonstration of the larvae in the granulomatous lesions or fistulous tracts is diagnostic. Biopsies of the affected tissue are directly examined for *Habronema* larvae and may also be submitted for histopathologic examination. Cytologic examination of conjunctival scrapings reveals a mixed inflammatory response, with neutrophils, eosinophils, and macrophages predominating; however, *Habronema* larvae are usually not seen. The differential considerations for these lesions include neoplasia (especially squamous cell carcinoma), sarcoids, phycomycosis, onchocerciasis, foreign body reaction, and exuberant granulation tissue.

39.44.5.27.8

Treatment

Until recently, routine treatment was topical, with systemic therapy reserved for severe or refractory cases. However, oral ivermectin (0.2 mg/kg) has become the treatment of choice. Lesions begin to regress in 7 days and are usually healed by 4 to 6 weeks after treatment. Other effective larvicides include trichlorfon, ronnel, and diethylcarbamazine (DEC).

Topical, intralesional, and systemic corticosteroids may be used to decrease the inflammatory response to the larvae, but with ivermectin larvicidal treatment, they may not be needed. Topical antibiotics are indicated and topical corticosteroids avoided if corneal ulceration is present. Debridement and drainage of granulomatous areas and fistulous tracts may increase topical drug penetration and prevent abscess formation. Fly control and prompt treatment of disorders causing ocular discharge or exposure of fresh tissue are important in prevention of habronemiasis.

1297 1298

39.44.5.27.9

Ocular Thelaziasis

Thelazia nematodes in the conjunctival sac of large animals are considered commensal but can cause clinical ocular disease. *Thelazia* species have a worldwide distribution, with *Thelazia lacrymalis* found more often in horses and *Thelazia gulosa, Thelazia rhodesii,* and *Thelazia skrjabini* found more frequently in cattle. The infection rate for cattle and horses in the United States is estimated at 15% to 38%, with horses less than 3 years of age affected more often than adult horses. The complete life cycle of the parasite is unknown, but *Muscae autumnalis* (face fly) and other *Muscae* species serve as the intermediate hosts.

39.44.5.27.10 Clinical Signs

Most horses and ruminants infested with *Thelazia* show no clinical signs. However, chronic conjunctivitis, conjunctival cysts, and superficial keratitis can occur, especially in the summer months when flies are active. The disease is often mild but can progress to cause corneal neovascularization, edema, and ulceration. Dacryocystitis from parasite migration in the nasolacrimal system occurs and is more common in cattle than horses. Migration into the lacrimal gland and its ducts is seen and theoretically may lead to keratoconjunctivitis sicca.[489]

39.44.5.27.11 Diagnosis

Direct visualization of the adult *Thelazia* worms in the conjunctival sac or nasolacrimal flushings is diagnostic. The parasites are motile unless topical anesthetic is used. Adult *Thelazia* are 8 to 18 mm long and milky white, and their cuticle contains prominent transverse striations.

39.44.5.27.12 Treatment

In cattle, both ivermectin and doramectin given systemically at 200 mg/kg are effective in eliminating *Thelazia*.[490,491] It is unclear if ivermectin therapy is effective in eliminating *Thelazia* in horses.[491] Alternatively, the parasites may be removed manually with saline flushes or forceps after topical anesthetic is administered, followed by topical ophthalmic organophosphate therapy.[492]

39.44.5.27.13 Ocular Elaeophoriasis

Elaeophoriasis, or “sore head,” is a disease of sheep that is caused by the nematode *Elaeophora schneideri*. Adult *Elaeophora* organisms are found in the common carotid and internal maxillary arteries of deer, where microfilariae are produced and migrate into the capillaries of the face and head. Biting flies of the genera *Hybomitra* and *Tabanus* transmit the microfilariae to new hosts. The disease is most prevalent in the fall and winter in western parts of the United States where sheep are grazed at high altitudes. *Elaeophora* infections in deer are usually not associated with clinical signs. In small domestic ruminants and elk, however, the migrating microfilariae can cause a hypersensitivity reaction in facial and ocular capillaries.

39.44.5.27.14 Clinical Signs

Migration of *Elaeophora* microfilariae in ocular capillaries leads to local inflammation. Although the uveal tract is affected more often, sheep with elaeophoriasis may develop chronic keratoconjunctivitis evidenced by epiphora, blepharospasm, conjunctival hyperemia, chemosis, and corneal opacities. Clinical signs of anterior uveitis caused by *Elaeophora* are nonspecific and include epiphora, blepharospasm, miosis, clouding of the anterior chamber, and cataract formation. Funduscopic changes indicative of chorioretinitis and optic neuritis are common and include retinal edema, pigment changes in the tapetal and nontapetal fundus, optic disc edema, and optic disc atrophy.[493]

39.44.5.27.15 Diagnosis and Treatment

Diagnosis depends on demonstrating the microfilariae in skin or conjunctival biopsies. Treatment of heavily parasitized animals may cause death by occlusion of the carotid arteries with *Elaeophora* adults. Drugs used in treatment include piperazine (50 mg/kg orally), DEC (100 mg/kg), and stibophen (35 mL intravenously). The efficacy of ivermectin to treat *Elaeophora* is unknown, but it is poor against other filarides. Symptomatic treatment of keratitis and uveitis is indicated.

39.44.5.27.16 Ocular Manifestations of Nasal Bots

Larvae of the arthropod *Oestrus ovis,* the sheep botfly, can aberrantly migrate up the nasolacrimal duct and enter the conjunctival sac, causing local inflammation. Conjunctival migration is accompanied by epiphora, conjunctival hyperemia, and chemosis. Finding the larvae within the conjunctival sac is diagnostic. Treatment consists of mechanical removal and topical or systemic organophosphates. The nasal botfly *Gedoelstia hassleri* is reported to cause ocular lesions in horses in South Africa.

39.44.5.27.17 Ocular Manifestations of Trypanosomiasis and Piroplasmosis

Many species of the protozoal blood parasite *Trypanosoma* can infect horses and ruminants, causing edema, hyperemia, and petechiation of the conjunctiva. Sheep infected with *Trypanosoma brucei* can develop keratoconjunctivitis and panuveitis, including chorioretinitis and optic neuritis. Demonstration of the organism in blood smears is diagnostic.

Other blood protozoans, including *Babesia* and *Theileria,* can also cause conjunctival edema, petechiation, icterus, swollen eyelids, and blood-stained tears.

39.44.5.28 Uveal and Retinal Parasitism

39.44.5.28.1 Onchocerciasis, Elaeophoriasis, and Trypanosomiasis

Onchocerca cervicalis causes equine parasitic uveitis and chorioretinitis, and *Elaeophora* and *Trypanosoma* cause uveitis in sheep. Ocular manifestations of these diseases are discussed under Corneal and Conjunctival Parasitism.

39.44.5.28.2 Toxoplasma Iridocyclitis and Retinitis

The intracellular protozoan parasite *Toxoplasma gondii* can cause ocular disease in large animals. Invasion and replication in the retina and uveal tract lead to retinitis, chorioretinitis, and anterior uveitis. The acquired form of toxoplasmosis in ruminants, however, is often not associated with clinical signs, and ocular lesions are uncommon. Toxoplasmosis is rare in horses.

39.44.5.28.3 Clinical Signs

The most common ocular findings with ocular toxoplasmosis are iridocyclitis and retinitis.[494] Retinitis is the primary posterior segment lesion, with secondary involvement of the chorioid. Retinal degeneration,

clumping of pigment in the retinal pigment epithelium and chorioid, and optic disc avascularity are seen ophthalmoscopically; however, these lesions are not pathognomonic for toxoplasmosis. Orbital pain and swelling may result from parasitic invasion of extraocular muscles and orbital fat.

39.44.5.28.4 Diagnosis and Treatment

39.44.5.28.4.1 MISCELLANEOUS INTRAOCULAR PARASITES

The most common intraocular parasite in horses is *Setaria,* with *Setaria digitata* found more frequently within the eyes of horses than *Setaria equina.* Ocular infestation is presumed to result from aberrant migration of the larval stage. Although *Setaria* causes minimal inflammation in the peritoneal cavity, it can cause serious intraocular inflammation. Diagnosis is by visualizing the parasite in the aqueous humor. Treatment involves symptomatic antiinflammatory therapy and surgical removal.

Other filarides found free within the anterior chamber of horses' eyes include *Dirofilaria immitis* and *Onchocerca cervicalis*. Diagnosis and treatment are the same as for *Setaria*. Severe endophthalmitis resulting from intraocular infection with the free-living nematode *Halicephalobus* has been reported in a horse.[495] The ocular disease was accompanied by a fatal encephalopathy. Diagnosis was based on finding the parasite during microscopic examination of intraocular tissues.

The canine cestodes, *Echinococcus granulosa* and *Echinococcus multilocularis,* may form intraocular hydatid cysts in horses and ruminants, thereby producing extensive inflammation and retinal detachment. There is no medical treatment, and surgical removal is often impossible. Diagnosis is made on histopathologic examination of affected tissues.

Coenurus cerebralis, the intermediate form of *Taenia multiceps* and *Taenia serialis,* can develop in the CNS of sheep, causing a disease known as "sturdy" or "gid." Besides having abnormal gait, affected animals are often centrally blind. No treatment exists.

39.44.5.28.4.2 OCULAR NEOPLASIA

STEVEN M. ROBERTS

A wide variety of tumor types may involve the ocular or periocular tissues of food animals. Except for the most common neoplasms, limited information is available regarding treatment modalities, drug dosages, overall prognosis, and prevention or control. The tendency has been to adapt information and methods used in other areas of medicine for use in large animals. Table 39-3 lists potential presenting signs and corresponding ocular neoplastic conditions or related differential diagnoses for horses, cattle, sheep, and goats. Table 39-4 categorizes ocular neoplasms that have been reported in the literature for each of these species. The greatest amount of information pertains to the horse.

Despite the variety of primary and secondary neoplasms affecting the ocular and periocular tissues, most tumors produce similar effects on the eye, with tissue distortion and loss of function being the initial concerns. Strategic therapy and management goals may vary from curative or palliative (e.g., eliminating discomfort by enucleation) for individuals to elimination of the problem (e.g., culling from the herd) for a population. Specific tumor treatment options are often similar for neoplasms involving a particular ocular region or location; when designing a management plan, however, the specific

histologic tumor type is important in determining prognosis. Classification of a tumor as "benign" versus "malignant" or "localized" (e.g., equine sarcoid) versus "systemic" (e.g., lymphosarcoma) greatly influences treatment options and management approaches. The following discussion addresses the major tumors of concern in large animals and briefly surveys miscellaneous tumors that have been associated with ocular signs.

Table 39-3 Ocular Neoplasia and Differential Diagnoses by Species Based on Presenting Clinical Signs

Clinical Sign	Equine	Bovine	Caprine	Ovine

39.44.6 OCULAR SQUAMOUS CELL CARCINOMA

39.44.6.1 Definition and Etiology

Bovine ocular squamous cell carcinoma (OSCC), also commonly called “cancer eye,” represents the most economically important neoplasm of large animals. It is the most common tumor affecting cattle in North America, and according to estimates from federally inspected abattoirs in the United States, 12.5% of all bovine carcass condemnations were caused by OSCC.[496] The economic impact includes carcass condemnations, production losses, treatment expenditures, and management costs.

Ocular SCC arises from the epithelial surfaces of the conjunctiva (corneoscleral junction, nictitating membrane, and palpebra) or cornea. The etiology is probably multifactorial, with genetic, environmental, and viral factors being proved or suspected.[496–498] In particular, increasing levels of solar irradiation and decreasing amounts of circumocular pigmentation are linked to an increased prevalence of OSCC.[499,500]

Equine OSCC is the most prevalent equine ocular neoplasm (followed by equine sarcoid) and typically occurs in horses with unpigmented eyelids.[498,501] The amount of perilimbal and nictitating membrane pigmentation represents another important causal factor in cattle and horses that has received little attention but should be considered on prepurchase and health examinations (see Chapters 1 and 2).

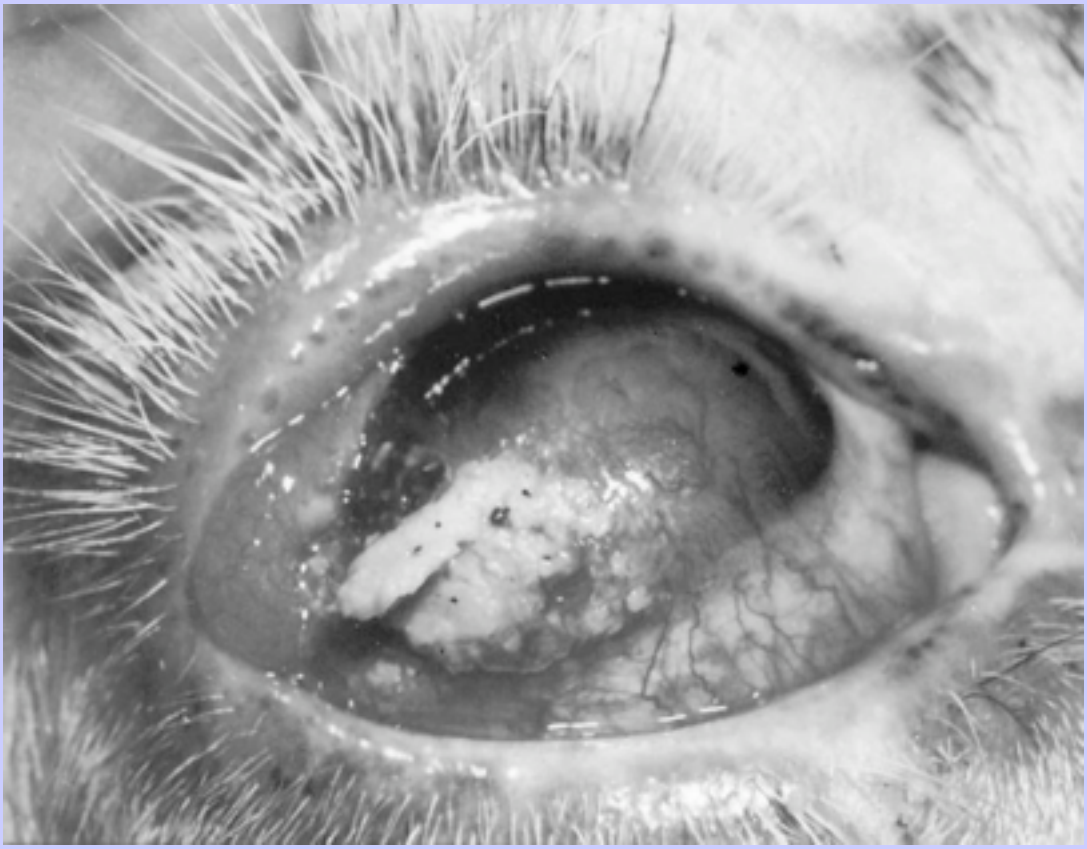
39.44.6.2

Clinical Signs and Differential Diagnoses

The gross appearance depends not only on the anatomic tumor site (because this determines the overall interaction between epithelium and underlying connective tissue elements) but also the stage of malignancy. In general, premalignant squamous cell tumors are small, white, elevated, hyperplastic plaques or papilloma-like structures with verrucous surfaces (Fig. 39-29). In contrast, malignant tumors are more irregular, nodular, pink, erosive, and necrotic in nature (Fig. 39-30). Necrotic tumors often have a characteristic foul odor. Squamous cell carcinomas that invade the orbit may become massive and eventually aggressively invade bone. Often the gross appearance allows a diagnosis to be established, but at times, cytology or histology is necessary to differentiate among benign tumors, carcinoma in situ, and invasive SCC. Bovine OSCC typically involves (in decreasing order of frequency) the lateral limbus, eyelid margins (especially the lower), nictitating membrane, and medial canthal regions.[496,497] Similar tissues are involved in horses, although some reports suggest that the nictitating membrane is more frequently involved than the corneoscleral junction.[498,502] Clinical signs resulting from metastatic lesions are not common, although lymphatic tissues may become infiltrated with neoplastic cells.

Fig. 39-29 Bovine ocular squamous cell carcinoma (OSCC). Note the small, premalignant, hyperplastic plaque involving the medial limbus and the large, malignant, nodular mass on the lower eyelid. The large mass is becoming ulcerated and necrotic.

Fig. 39-30 Bovine OSCC involving the cornea and conjunctiva. Note the irregular and invasive growth into the cornea. The surface is rough and necrotic.



1301

1302

Despite the characteristic appearance of lesions, differential considerations (especially in the horse) include adenocarcinoma, adenoma, angiosarcoma, basal cell tumor, conjunctival follicular hyperplasia, dermoid, fibroma, fibrosarcoma, granulation tissue, habronemic blepharoconjunctivitis, lymphosarcoma, mastocytoma, plasma cell tumors, sarcoid, and schwannoma (see Tables 39-3 and 39-4).

39.44.6.3

Pathophysiology

The tumor in all species develops through a series of premalignant stages (i.e., hyperplastic plaques or epidermal plaques and papillomas) to progress over months and years to a carcinoma in situ and finally an invasive squamous cell carcinoma. Neoplastic lesions may arise without notable precursor stages. It is unlikely that tumors arise in the cornea unless previous vascularization has occurred.[503] Spontaneous regression of 30% to 50% of bovine precancerous lesions may occur,[496] and in rare cases, early OSCC may regress spontaneously. Tumors arising at the limbus are confounded by the dense and poorly vascularized sclera and cornea, thus hindering metastasis to extraocular sites. Nictitating membrane tumors extend to the base of the membrane and cartilage more rapidly, with spread into the orbit and surrounding bones occurring

much sooner than with tumors involving the globe. Although metastasis will eventually occur, extensive extraocular spread is limited in cattle by the practice of sending most affected animals to slaughter. Horses demonstrate multiple tumor locations and local invasion in up to 50% of cases.[502,503] Metastasis beyond extraocular sites is rare in horses.

39.44.6.4

Epidemiology

Although OSCC has been reported in a wide variety of cattle breeds, the Hereford breed (either purebred or crossbred) is most often diagnosed with this tumor as a result of the common use of this breed as a range animal and the strong genetic trait for a white face. Thus, selective breeding for partially to fully pigmented periocular skin greatly reduces the occurrence of this tumor.[496] The tumor is more common in older cattle, with the peak age prevalence being 7 to 8 years. Exposure to increasing levels of actinic radiation raises the prevalence of bovine OSCC.[499] The prevalence of ocular squamous cell tumors, including nonmalignant tumors, involving Hereford herds in regions with abundant sunlight can range from 20% to 40%. Research performed in cattle herds suggests that a high plane of nutrition or a lower-than-normal body weight in cows for the first 2 years acts to increase the prevalence.[496] The intriguing possibility that bovine OSCC may be induced by viruses (e.g., papillomavirus) warrants further research.

Equine OSCC in North America demonstrates an increased prevalence with increasing longitude (°W), altitude, and mean solar irradiation.[501] Breeds with a greater risk of developing OSCC include draft breeds, especially the Belgian (odds ratio [OR] = 21.7), Appaloosa (OR = 7.9), paint and pinto (OR = 4.5), and grade horses (OR = 3.1). Coat colors showing an increased risk include white (OR = 26.7), creamello/palomino (OR = 13.7), gray (OR = 6.7), red/white and strawberry/white (OR = 4.7), buckskin (OR = 4.4), and chestnut/sorrel (OR = 3.8).[501]

39.44.6.5

Necropsy Findings

Depending on the extent of involvement, gross changes are noted that involve the globe, conjunctiva and nictitating membrane, orbit, bones of the orbit, and regional cervical lymph nodes. In rare instances, metastasis to thoracic and abdominal organs can occur.

39.44.6.6

Treatment and Prognosis

Numerous modalities are available, and applications depend on availability of instrumentation, location and extent of the tumor, and value and intended function of the animal. Choices include radiofrequency hyperthermia,[*] cryonecrosis, intralesional injection of biologic response modifiers (BRMs; e.g., allogeneic OSCC extract, mycobacterial cell wall fraction,[†] *Propionibacterium acnes*[‡]), intralesional chemotherapy with cisplatin[§] (with or without initial debulking),[504,505] radiotherapy (cesium-137, cobalt-60, gold-198, iridium, strontium-90), and surgical removal (local excision, enucleation, and exenteration with or without salivary gland and lymph node resection). Intralesional use of cisplatin (1 mg/cm^3 of tumor volume) is highly effective, but multiple injections are necessary (four times at 2- to 3-week intervals). Handling of the drug and animal after treatment must adhere to U.S. Occupational Safety and Health Administration (OSHA) guidelines,[506] and animals must not be used for food consumption. Appropriate precaution should be followed with extralabel use of cytotoxic drugs. Surgical debulking with adjunctive cryonecrosis or radiofrequency hyperthermia is an effective and affordable treatment modality. Cryonecrosis is achieved with

liquid nitrogen, using a probe or spray delivery system to freeze the tissues to −30° C (−22° F) twice, with complete thawing between freeze cycles. Radiofrequency hyperthermia is performed with piercing or surface probes to heat the tissues to 50° C (122° F) for 30 seconds. Multiple treatment sites are necessary for lesions larger than 0.5 cm in diameter.

Because recurrence rates range between 30.4% and 42.4%,[498,502] the willingness of the owner to return the animal for follow-up treatment is a significant determinant in overall survival. Financial constraints were the most common reason for cessation of treatment. Many horses that die as a consequence of OSCC are euthanized at the owner's request. The overall prognosis is determined by the degree of neoplastic involvement of normal tissue, but a guarded prognosis is warranted. If treatment is to be undertaken, intervention should begin at the earliest stages of tumor development. In animals destined for slaughter, the guidelines for condemnation of bovine carcasses affected with OSCC shown in part A of Box 39-2 should be considered.

39.44.6.7

Prevention and Control

In cattle, factors such as genetics, UV light, and environmental factors (e.g., wind, dust) are known to be involved in OSCC. Ocular viral infection may also be contributory. If possible, affected animals should be culled as soon as possible because most production situations preclude environmental factor modification. Specific preventive measures have not been systematically evaluated in horses, but recommendations include reducing UV light exposure, using protective fly masks in horses (to decrease solar irradiation and environmental irritants), tattooing lightly pigmented periocular skin, and avoiding breeds thought to have an increased risk of tumor development.

39.44.7

OCULAR MANIFESTATIONS OF LYMPHOSARCOMA

39.44.7.1

Definition and Etiology

Lymphosarcoma is a fatal systemic neoplastic disease of the lymphoreticular tissue. The adult or enzootic form of bovine lymphosarcoma is likely the most devastating and common neoplasm of dairy cattle. This is a systemic disease with ocular manifestations rather than a pure ophthalmic problem. (See Chapter 37 for specific information regarding bovine lymphosarcoma and the bovine leukemia virus.) Lymphosarcoma represents the most common cause of orbital neoplasia in cattle,[507] excluding OSCC that involves the orbit by local extension. Lymphosarcoma may affect horses[508] and goats. The etiology in horses and goats is unknown.

1302

1303

39.44.7.1.1

Box 39-2 Guidelines for Inspection (Antemortem and Carcass) and Disposal of Animals, Carcasses, and Parts Affected with Neoplasia

A Epithelioma of the eye

1 Any animal found on antemortem inspection to be affected and the eye has been destroyed or obscured by neoplastic tissue and which shows extensive infection, suppuration, and necrosis, usually accompanied by foul odor, or any affected animal with cachexia, regardless of extent, shall be condemned.

2 Carcasses of animals with the eye or orbital region affected will be condemned if the affection has:

a Involved the osseous structures of the head with extensive infection, suppuration, and necrosis;

b Metastasized from the eye or orbital region to any lymph node (including the parotid lymph node), internal organs, muscles, skeleton, or other structure, regardless of the extent of the primary tumor; *or*

c Regardless of extent is associated with cachexia or evidence of absorption or secondary changes.

3 Carcasses of animals affected to a lesser degree than above may be passed for human food after removal and condemnation of the head, including the tongue, provided the carcass is otherwise normal.

B Neoplasms

1 An individual organ or other part of a carcass affected with a neoplasm shall be condemned. If there is evidence of metastasis or that the general condition of the animal has been adversely affected by the size, position, or nature of the neoplasm, the entire carcass shall be condemned.

2 Carcasses affected with malignant lymphoma shall be condemned.

From *Code of Federal Regulations,* Title 9, Chapter 3, Parts 309.6, 311.11, and 311.12 (1-1-87 edition).

39.44.7.2

Clinical Signs and Differential Diagnoses

Clinical signs are usually associated with exophthalmos caused by orbital disease. Neoplastic lymphoid cell infiltration behind the globe results in exophthalmos, subsequent exposure keratitis, and eventual proptosis[507] (Fig. 39-31). One report has documented intraocular lymphosarcoma in a Holstein cow as the presenting sign of generalized lymphosarcoma.[509] Subtle exophthalmos is often overlooked because of the natural exophthalmic state of some dairy breeds. Typically, these animals present with a history that suggests an acute onset of exophthalmos, when actually orbital involvement has been present for a time. Clinical signs associated with the exophthalmos and exposure keratitis include corneal edema, vascularization, ulceration, epidermalization, conjunctival hemorrhage, chemosis, and ocular discharge. These signs may develop, progress, and change quickly once corneal protection is compromised. Other physical examination findings are discussed in Chapter 37. Differential considerations for exophthalmos include orbital cellu-litis, trauma, retrobulbar hemorrhage, retrobulbar soft tissue masses, chronic sinusitis, and sinus neoplasia (see Tables 39-3 and 39-4).

Fig. 39-31 Orbital lymphosarcoma. Diffuse orbital involvement causing exophthalmos and secondary exposure keratitis of the right eye.

39.44.7.3

Clinical Pathology

Definitive diagnosis is achieved by cytologic samples obtained with a spatula after topical anesthesia[496] or specimens excised for biopsy and fixed in formalin. Benign lesions typically contain superficial, anucleated, keratinized squamous cells and deeper epithelial cells with enlarged nuclei and coarse chromatin clumping. Biopsies of these lesions show that the basal layer or basement membrane has not been invaded. Malignant OSCC lesions are composed of pleomorphic cells with bizarre shapes, large hyperchromatic nuclei containing large clumps of chromatin, and prominent nucleoli. On biopsy examination, invasion across the basement membrane is noted, and keratin-pearl formation or marked anaplasia is usually present.[503] In the event of regional lymphatic involvement, fine-needle aspiration or preferably a biopsy may demonstrate neoplastic infiltration.

Equine lymphosarcoma involving the eye also represents a systemic disease with ocular manifestations. Other systemic manifestations are discussed in Chapter 37. Ocular lesions include uveitis, nictitating membrane masses, chemosis and conjunctivitis, and neoplastic infiltration of the eyelids and orbit.[509] Differential considerations should include any chronic inflammatory disease, equine infectious anemia, equine piroplasmosis, and infectious causes of uveitis (see Table 39-2).

39.44.7.4 Necropsy Findings

As with the clinical signs, necropsy findings are variable. In cattle, orbital involvement is common, with lymphoid tumors being firmly attached to the periorbita and walls of the orbit. Extraocular muscles are frequently infiltrated with tumor cells. The globe itself is typically not involved.[503] Ocular lesions occur less often in horses than in cattle. In the horse the globe (uveal tract) can be involved, in addition to extraocular tissues. As with other systemic neoplastic diseases, multiple organ involvement is expected with lymphosarcoma.

39.44.7.5 Treatment and Prognosis

This systemic disease may be treated palliatively or systemically in an attempt to achieve remission for a time. Enucleation provides palliative treatment, and chemotherapy with corticosteroids, vincristine, and L-asparaginase may induce remission. Extralabel use of these cytotoxic drugs must be approached with extreme caution, and treated animals must not be used for food consumption. Most cattle with orbital lymphosarcoma either die or are euthanized in terminal stages of disease within 6 months of the original diagnosis.[507] Horses can have a much more protracted disease course, with many presenting because of chronic illness of up to 12 months' duration.[508] The overall prognosis is unfavorable, regardless of the species involved.

1303 1304

39.44.7.6 Prevention and Control

Control of bovine lymphosarcoma depends on efforts to eradicate bovine leukemia virus, a monumental task in most cases. In other large animal species, prevention and control recommendations for lymphosarcoma are not possible until the etiology can be identified. If animals are destined for slaughter, the guidelines for condemnation of bovine carcasses affected with lymphosarcoma as shown in part B of Box 39-2 should be followed.

39.44.8 OCULAR MANIFESTATIONS OF EQUINE SARCOID

39.44.8.1 Definition and Etiology

Equine sarcoid is a locally aggressive, nonmalignant, fibroblastic tumor of the equine skin (see Chapter 40). It appears to be the most common equine neoplasm, with 14.7% of ocular and adnexal tumors in the horse being sarcoids (all involved the eyelids).[510] This neoplasm develops more frequently in sites predisposed to trauma and areas that come into contact with existing sarcoids, and it does not metastasize to internal organs.

39.44.8.2 Clinical Signs and Differential Diagnoses

Sarcoids involving the eyelids are classified according to the scheme used for cutaneous lesions: verrucous, fibroblastic, mixed, or occult. Tumors of the eyelids may appear smooth and nodular, crusted and nodular, ulcerated, or pedunculated (Figs. 39-32 and 39-33). Regardless of their appearance, the tumors are nonregressing. Periocular sarcoids are subject to trauma; thus the verrucous type frequently transforms into the fibroblastic type with surface ulceration. It is difficult to differentiate sarcoid from fibroma, fibrosarcoma,

neurofibroma, neurofibrosarcoma, schwannoma, or nonneoplastic granulation tissue (see Tables 39-3 and 39-4).

39.44.8.3 Treatment and Prognosis

Problematic lesions can be treated by a variety of modalities, none of which is uniformly successful. Often, multiple treatment sessions are required for tumor control. Treatment modalities include surgical excision (50% success rate), cryonecrosis (30% success rate), radiofrequency hyperthermia (RDM Hypertherm), intralesional injection of BRMs (bacille Calmette-Guérin),[510] chemotherapy with intralesional cisplatin (Platinol; with or without initial debulking),[503,504] radiation therapy (cesium-137, cobalt-60, gold-198, iridium, strontium-90), and chemotherapy (5-fluorouracil) combined with surgical excision. BRM therapy has not proved as successful for sarcoids located at other body sites. An available commercial *Mycobacterium* product (Normagen) can be used, but it does not demonstrate the clinical efficacy seen with previously used research preparations. If the sarcoid is static, flat, and hairless, it may be best left alone because any trauma, surgical or otherwise, could increase the growth rate and invasiveness of the lesion. Response to therapy varies on the basis of tumor location, duration, severity, and previous therapeutic measures.

Fig. 39-33 Equine sarcoid involving the medial aspect of eyelid. At examination or during treatment, sarcoids may become ulcerated. This tumor became ulcerated after one injection of a *Mycobacterium* cell wall preparation but subsequently resolved.

Fig. 39-32 Equine sarcoid. The upper eyelid exhibits a smooth, nodular mass typical of many periocular sarcoids.

Treatment of periocular sarcoid with BRMs shows particular promise but has the disadvantage of requiring a potentially long course of treatment, involving a series of intralesional injections. Intratumoral use of cisplatin is highly effective (see Chapter 40). Successful treatment measures exist for equine sarcoid, and if a complete treatment protocol is followed, the prognosis is favorable. As with any neoplastic disease, at the first evidence of recurrence, the animal should be reevaluated.

39.44.9 MISCELLANEOUS TUMORS WITH OCULAR INVOLVEMENT

The tumors previously discussed represent the most significant ocular or periocular neoplasms of large animals. However, to the individual animal or owner, any tumor type represents a significant problem. Thus, clinicians must remember that numerous primary and secondary neoplastic processes can involve the eye and surrounding tissues. Secondary tumors may be either metastatic masses or locally invasive masses extending from sites near the eye. The greatest variety of ocular neoplastic disease has been reported in the horse (see Table 39-4).

Adnexal tumors that have been reported include adenoma, adenocarcinoma, basal cell carcinoma, fibroma, fibrosarcoma, hemangioma,[511] hemangiosarcoma,[512] lymphosarcoma, melanocytoma, melanoma, papilloma, plasma cell tumors, and schwannoma. Few reports address treatment of these tumors thoroughly. 1304 1305

Surgical excision of small lesions, cryosurgery, radiation therapy, intralesional cisplatin,[504,505] and medical treatment with cimetidine[513,514] have been used successfully on select tumors. Oral cimetidine (2.5 mg/kg three times daily for an initial 3-month period) is useful as a means of melanoma control. If lesions are progressively enlarging, cimetidine has been particularly successful in arresting or resolving tumor lesions. This treatment is also a useful adjunct to cryonecrosis, surgical excision, or chemotherapy. The prognosis is poor for malignant masses because metastatic disease or local recurrence usually results. This is especially true with angiosarcomas[502] that involve primarily the conjunctiva but may also involve the corneoscleral junction. Limited success with angiosarcoma treatment has been achieved in a case of equine orbital lymphangiosarcoma through enucleation and chemotherapy with intravenous vincristine (four doses of 1.3, 1.3, 1.2, and 1 mg/m^2 of body surface area on days 0, 7, 14, and 51, respectively) and prednisone. Seven years after treatment, the horse showed no signs of recurrence. An additional case of conjunctival and nictitating membrane malignant hemangiosarcoma was treated by local excision and perioperative intratumoral cisplatin. Follow-up demonstrated tumor lysis and no recurrence after 6 months.

Any tumor involving the nasal and paranasal cavities has the potential to involve the ocular structures as the result of orbital spread. Enzootic adenocarcinoma in sheep is an example of this type of process. Although infrequently noted, exophthalmos secondary to orbital invasion of this tumor has been reported.[515] Primary orbital neoplasia in the form of a multilobular osteoma (chondroma rodens) has been reported in the horse[516] and reminds one that a space-occupying mass (neoplasia) can affect the eye by causing progressive exophthalmos.

Neoplasia involving the CNS, diencephalon, or occipital cortex can result in a central blindness, abolished pupillary light responses, and mydriasis. Other forms of intracranial neoplasia can secondarily involve the eye as a result of cranial nerve dysfunction. For example, an intracranial schwannoma caused exposure ulcerative keratitis in a cow that presented with left facial paresis.[517]

Reports of neoplasia involving the globe, all in horses, describe the clinical, histologic, and treatment aspects of epibulbar melanocytoma,[518] intraocular melanoma,[519,520] and medulloepithelioma.[521] Optic nerve tumors have included neuroepithelial tumors and meningiomas. In the intraocular cases the globe was rendered nonfunctional by the neoplastic process, and the involved eye was subsequently enucleated. An optic nerve neuroepithelial tumor displayed metastatic spread as a result of extension into the brain through the optic foramen, causing brain compression.[522] Although documented cases of these miscellaneous ocular neoplasms are not widespread, they must be taken into consideration as possible causes of large animal ocular neoplasia.

Other than vascular tumors, most ocular tumors do not display a severe metastatic threat. Although enucleation may be curative, histologic evaluation of excised tissues and long-term patient follow-up are necessary if accurate epidemiologic and prognostic data are to be available. Once an accurate diagnosis has been made, the clinician and owner must determine, in light of all available medical information and the proposed use of the animal, whether treatment should be curative or palliative or whether elimination of the problem from the herd should be of greater concern than care of the individual animal.

Stephen D. White

40.1 IMMUNE-MEDIATED SKIN DISORDERS

STEPHEN D. WHITE

40.2 PEMPHIGUS FOLIACEUS

40.2.1 Definition and Etiology

The term *pemphigus* is derived from the Greek word for "blister" and is used to describe a group of autoimmune vesiculobullous disorders characterized histologically by intraepidermal acantholysis and immunologically by intercellular deposition of immunoglobulin. Pemphigus foliaceus is the most common of this group of autoimmune diseases; in large animals it has been reported in horses,[1,2] goats,[3,4] and a donkey.[5] In small animals, pemphigus foliaceus has been putatively associated with drugs,[6] but this has not been identified in large animals. The factors precipitating the development of pemphigus foliaceus in large animals are unknown. The clinical lesions recognized in horses and goats are primarily scaling and crusting.

40.2.2 Pathophysiology

Pemphigus foliaceus is characterized by the production of autoantibodies. In humans and dogs, these are directed against transmembrane proteins (desmoglein 1 in humans and a minority of dogs). The pemphigus autoantibody binds to the transmembrane protein, resulting in the release or activation of one or more proteolytic enzymes. These enzymes destroy the attachments between adjoining epidermal cells. The result is *acantholysis;* the epidermal cells assume a rounded shape and separate from one another, leading to the formation of intraepidermal clefts and vesicles.[7]

40.2.3 Clinical Signs

Pemphigus foliaceus is characterized clinically as a generalized exfoliative dermatitis (Fig. 40-1). Ventral or peripheral limb edema and crusts are the most common clinical signs.[1] In one recent study, no age, breed, or gender predilection was noted, although (80%) of affected horses first exhibited signs between September and February.[1] In the horse, lesions are usually first noted on the head, limbs, or ventrum. Initial lesions also may be associated with fever, depression, or rarely urticaria. The disease usually progresses to involve the entire body over days to weeks. The primary lesion is a pustule, but these are fragile and transient lesions. Pustules rupture soon after formation, resulting in erosions, epidermal collarettes (rings of exfoliating superficial epidermis), scale, and crust. The lesions may or may not be associated with pruritus or pain.[1,2*]

In the goat, pemphigus foliaceus also presents as a generalized exfoliative dermatitis. In the limited number of cases described, lesions were initially noted on the limbs, perineal region, and ventrum. The lesions consisted of

crusting and scaling resulting from rupture of vesicles and bullae. Pruritus and malaise appear to be variable findings.[3]

* Portions of this chapter are adapted from previous editions, which were written by Anne G. Evans, DVM.

40.2.4 Diagnosis

Diagnosis of pemphigus foliaceus in large animals is typically based on biopsy of lesions submitted for routine histopathology. Characteristic histologic findings include intragranular to subcorneal cleft and vesicle formation associated with acantholysis. Both follicular and surface epithelia are frequently involved. Neutrophils tend to predominate in the inflammatory infiltrate, although eosinophils may also be present.[1–3] Because certain strains of *Trichophyton* species of dermatophytes may also cause acantholysis, any histology suggestive of pemphigus foliaceus must be stained for fungi.[8] Direct immunofluorescence or immunohistochemistry as an aid in the diagnosis of pemphigus foliaceus in horses and goats has also been reported but is somewhat limited to research and academic institutions.[3,7,9] Indirect immunofluorescence testing (for pemphigus antibodies in serum) is reported to be unreliable for the diagnosis of pemphigus foliaceus in horses.[7,10]

40.2.5 Therapy

Treatment is corticosteroids at immunosuppressive doses, such as prednisolone at 1 mg/kg every 24 hours (q12h) or dexamethasone at 0.08 to 0.1 mg/kg q24h, then tapering. Oral prednisolone is preferred to prednisone because some horses are unable to metabolize prednisone into the active metabolite of prednisolone.[11] Injectable gold (Solganal, Schering) was also used successfully, but this product is no longer available. There are anecdotal reports of benefits using another gold salt, aurothiomalate (Myochrysine, Rhône-Poulenc Rorer), 1 mg/kg intramuscularly (IM) every 7 days. Gold salts take 1 to 3 months to reach effectiveness, when dosage frequency can be tapered to every 14 to 30 days. Adverse reactions of gold salts, although rare in the horse, include thrombocytopenia and glomerulonephropathy.

There are also reports of azathioprine (1 to 3 mg/kg q24-48h) being used for various autoimmune skin diseases in horses.[12,13] A potential side effect is thrombocytopenia because horses have low levels of the enzyme thiopurine methyltransferase (TPMT),[14] which is responsible for the metabolization of azathioprine in other species, including humans. However, I have administered azathioprine (1 to 3 mg/kg for 1month, then q48h) to eight healthy horses with no deleterious effects.[15] Azathioprine is used as a steroid-sparing drug with corticosteroids, eventually to decrease the steroid needed. Approximate cost in a 500-kg horse for daily azathioprine is $300/month.

1306

1307

Fig. 40-1 Pemphigus foliaceus in a horse; note generalized crusts.

Goats have also been treated successfully with corticosteroids (dexamethasone, prednisolone) and aurothioglucose.[3,4,9] Dosages approximate those for the horse.

40.2.6 Prognosis

The response to treatment in equine pemphigus foliaceus varies from patient to patient. Many horses require lifelong administration of medication to control the clinical signs; others may be gradually weaned from medication without further relapse. In one study in which follow-up information was available for 13 horses, four were euthanized because of complications from the disease or its treatment. The reported cases of caprine pemphigus foliaceus are insufficient in number to establish a prognosis reliably.

40.3 BULLOUS PEMPHIGOID

Bullous pemphigoid is an autoimmune, vesiculobullous, and ulcerative disorder that affects the cutaneous basement membrane zone (BMZ). It has been rarely noted in horses.[7,16] Initiating triggers for the disease in the horse are unknown.

The pathophysiology of bullous pemphigoid in horses is assumed to be similar to that described in other mammals. Complement-activating anti-BMZ antibodies bind to a glycoprotein antigen in the lamina lucida of the BMZ. In horses, this has been shown to be bullous pemphigoid antigen II (also called collagen XVII). Complement activation results in degranulation of mast cells and chemotaxis of neutrophils and eosinophils. Eosinophils release tissue-destructive enzymes with resultant injury to the BMZ, loss of dermoepidermal adherence, and subsequent blister formation.[7]

Equine bullous pemphigoid is characterized clinically by painful, crusted, or ulcerative lesions of the skin (face and axillae), mucous membranes, and mucocutaneous junctions. Bullae are rare.[7,16] Ulceration may involve the gastrointestinal (GI) tract. The diagnosis is based on histopathologic and, when available, immunofluorescent findings. Treatment is the same as for pemphigus foliaceus; the few cases reported have not had favorable outcomes, but I have seen a case that initially responded well to corticosteroids.

40.4 HYPERSENSITIVITY DISORDERS

STEPHEN D. WHITE

40.5 ATOPIC DERMATITIS

40.5.1 Definition and Etiology

Atopic dermatitis may be defined as an abnormal immunologic response to environmental allergens, such as pollens, barn dust, and molds. It is increasingly being recognized as a cause of pruritus in horses. The disease may be seasonal or nonseasonal, depending on the allergen(s) involved. Age, breed, and gender predilections have not been extensively reported. A familial predisposition may be present.[17]

The presumed etiology is a type I (immediate) hypersensitivity response, mediated by immunoglobulin E (IgE). Although evidence indicates that atopic horses do produce allergen-specific IgE,[18] etiology is largely extrapolated from other species. The IgE is presumed to be directed against specific allergens. When that allergen is bound to two or more IgE antibodies on the surface of a mast cell, the mast cell releases granules containing various substances that cause erythema, vascular leaking, and pruritus.

40.5.2 Clinical Signs

Pruritus, often affecting the face, distal legs, or trunk, is the most common clinical sign. Alopecia, erythema, urticaria, and papules may all be present. Urticarial lesions may be severe but nonpruritic. Horses may have a secondary pyoderma, typified by excess scaling, small epidermal collarettes, or encrusted papules (“miliary dermatitis”). Diagnosis of atopic dermatitis is based on clinical signs and the exclusion of other diagnoses, especially parasite *(Culicoides)* allergy.

40.5.3 Diagnosis

Diagnosis is based on clinical signs and exclusion of other pruritic skin disease. Confirmation to formulate allergen-specific immunotherapy (ASIT, “hyposensitization”) is based on either intradermal testing (IDT) or serum allergy tests. The IDT involves a series of intradermal injections of aqueous allergen extracts along with a positive (histamine) and negative (saline) control. The injections are usually performed over the lateral cervical or thoracic region. The injection sites are then observed for 30 minutes to 24 to 48 hours for evidence of wheal formation associated with the injection site. A positive reaction does not necessarily mean that the horse's clinical signs are caused by the reacting allergen, but rather that the horse has antibodies to the allergen that, on intradermal exposure, trigger those clinical signs. False-negative IDT reactions may occur, the most important cause of which is the use of corticosteroids, antihistamines, or phenothiazine tranquilizers before testing.

Thus, although horses with atopic dermatitis generally have a higher incidence of positive reactions than healthy horses, the diagnosis (as in other species) cannot be solely made on the basis of the IDT or serologic test alone; rather, these tests should be interpreted in light of the history of the disease; for example, a horse with seasonal signs is more likely to have an allergic response to seasonal allergens (pollens in summer, barn dust in winter). This interpretation thus will help the clinician determine which allergens might be relevant in hyposensitization, should the owners choose that treatment.[18–21]

There is continuing controversy in the horse (and other domestic species) in regard to IDT versus the serologic tests available. These tests look for the allergen-specific IgE in the animal's blood.[22] I have used serologic tests as the basis for determining the allergens to be used for hyposensitization when the owner did not want the horse shaved for the IDT or the horse was receiving antihistamines. Preferentially, IDT and/or serologic testing is performed on horses with atopic dermatitis and with owners who are interested in pursuing hyposensitization. It should be remembered that in regard to food allergy, neither serologic testing nor IDT likely has any relation to reality. Clinical research is ongoing to determine the most important allergens, their testing dilutions, and effective control substances.[23,24]

1307 1308

40.5.4 Therapy

Corticosteroid treatment is usually effective in the control of pruritus or urticaria resulting from atopic dermatitis. The usual oral medication used is prednisolone (1 mg/kg q24h), although dexamethasone (0.05 mg/kg q 24h) may also be used. The injectable dexamethasone solution may be used orally, although the clinician should remember that the bioavailability is 60% to 70% of the injectable route.

Corticosteroids in horses may cause various adverse effects, including steroid hepatopathy, laminitis, and iatrogenic hyperadrenocorticism. Therefore, other modalities of treatment may be used, such as the antihistamines hydroxyzine pamoate (200 to 400 mg/500 kg q12h), or cetirizine (0.2 mg/kg q12h), doxepin (a tricyclic antidepressant with antihistaminic effects; 300 to 600 mg/500 kg q12h), or diethylcarbamazine syrup (6 to 12 mg/kg q24h). Hydroxyzine, cetirizine, and doxepin may cause either drowsiness or nervousness, although these adverse effects are uncommon. Some clinicians have noted improvement when an essential fatty acid (EFA) product is added to the feed; Platinum Performance has been used successfully in some atopic horses as an adjunctive treatment.*

In general, hyposensitization injections for any manifestation of atopic dermatitis in the horse should be evaluated for efficacy for at least 12 months. The veterinarian should maintain consistent communication with the client to monitor the progress of treatment and encourage the owner to continue with the injections for the full year. If hyposensitization is successful, it is thought that, as in other domestic species, most horses will need to be maintained on the injections for life, although sometimes at a reduced frequency (one to three times monthly). Approximately 70% of the owners of atopic horses at the Veterinary Teaching Hospital, School of Veterinary Medicine, University of California, Davis (UCD), that have had IDT or serologic testing have elected to try hyposensitization. In general, I find that approximately 60% to 70% of atopic horses improve with hyposensitization[25]; other researchers have reported even better results, but in a noncontrolled study.[26]

40.5.4.1

Box 40-1 Possible Causes of Urticaria in Horses and Ruminants

40.5.4.1.1

ALLERGIC URTICARIA

40.5.4.1.1.1

Inhalants

Pollens, animal danders, mold spores, feather down, aerosols, smoke, dust, and volatile chemicals

40.5.4.1.2

Injectants

Drugs, diagnostic agents, vaccines, insect stings, serums, and blood

40.5.4.1.3

Ingestants

Drugs, various food items, beverages, and occult additive materials found in foods

40.5.4.1.4

Infections

Foci of bacteria, fungal, viral, and parasitic infections

40.5.4.1.5

Contactants

Animal products, plant materials, cosmetics, plastic, and other chemicals

40.5.4.1.6

Drugs

Penicillin, aspirin, quinine, sulfonamides, insulin, and many others

40.5.4.1.7 Milk Proteins

Milk retention (cattle)

40.5.4.1.8 URTICARIA CAUSED BY URTICARIOGENIC MATERIALS

40.5.4.1.8.1 Drugs

Cocaine, morphine, codeine, atropine, quinine, thiamin, pilocarpine, polymyxin B, D-tubocurarine, dextran, dehydrocholate sodium (Decholin), and other drugs

40.5.4.1.8.2 Foods

Certain citrus fruits, strawberries, and certain fish

40.5.4.1.8.3 Toxins

Cobra venoms, jellyfish toxin, and certain plant and insect toxins

40.5.4.1.9 PHYSICAL URTICARIA

Dermographic (induced by blunt-scratch injury)

Heat

Cold

Light

Erythema multiforme

Pemphigus foliaceus

40.5.4.1.10 SECONDARY URTICARIA

Infections

Collagen vascular disease

	Neoplasia
	Psychogenic

40.6 URTICARIA

40.6.1 Definition and Etiology

Urticaria is characterized by transient focal swellings in the skin or mucous membranes called *wheals,* which represent localized areas of dermal edema. Angioedema is essentially identical but involves the subcutaneous tissues. The swelling of angioedema is diffuse, often involving the entire face and neck of the animal.

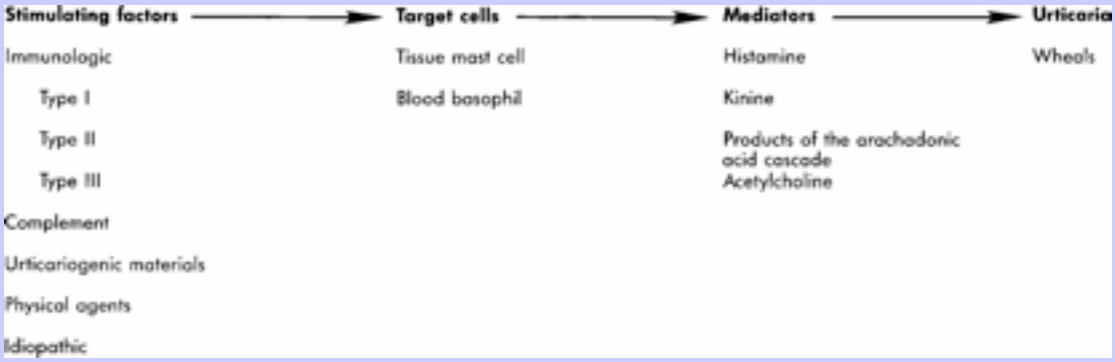
Urticaria is more frequently recognized in the horse than in ruminants. *Allergic* urticaria is usually caused by atopic dermatitis (environmental allergens such as pollens),[17,20,21,27] drug eruptions (especially antibiotics and nonsteroidal antiinflammatory drugs), contact allergies, and food allergies (rarely).[7]

Physical urticarias are less common and involve a nonimmunologic pathogenesis. The three most important categories include mechanically induced, such as dermatographism, essentially a "pressure" urticaria; cold urticaria; and exercise-induced urticaria. Miscellaneous diseases that can cause urticaria include dermatophytosis (initial lesions),[28] pemphigus foliaceus, "stress" (sometimes seen in racehorses immediately before a race), and vasculitis (Box 40-1). Urticaria is a recognized manifestation of milk allergy in cattle.[29]

1308

1309

Fig. 40-2 Flow of pathophysiologic events in the development of urticaria.



40.6.2 Pathophysiology

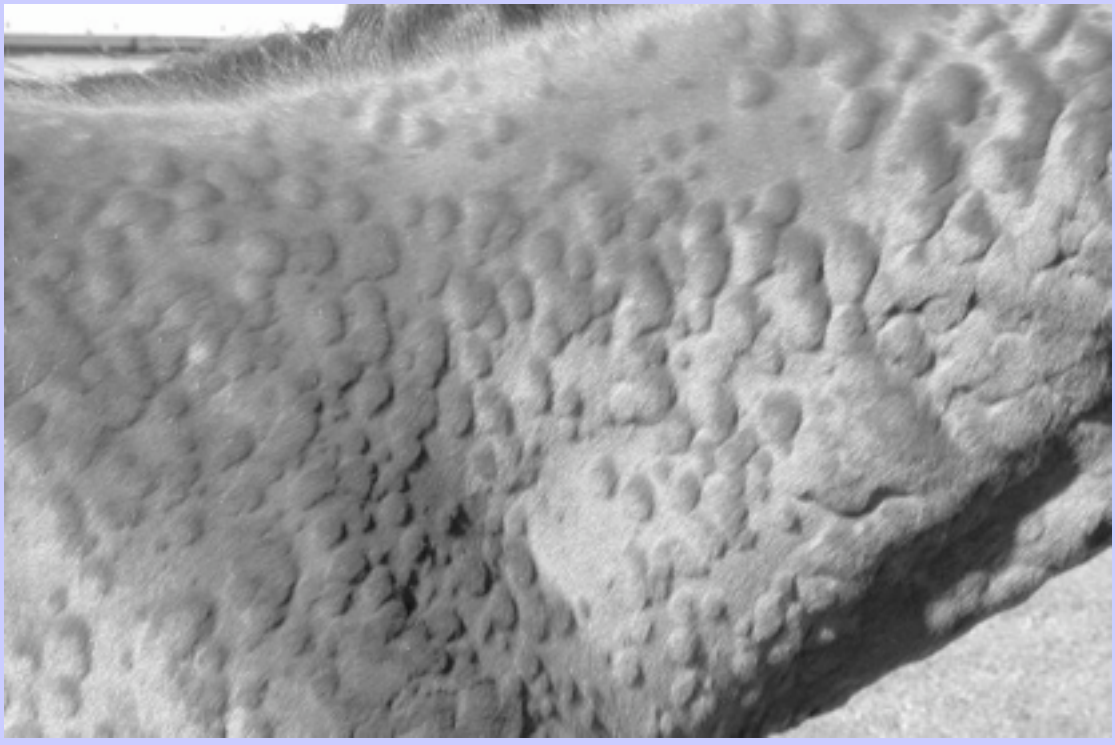
The wheals result from vasodilation and transudation of fluid from capillaries and small blood vessels. Both immunologic and nonimmunologic factors can trigger the release of mediators from mast cells and blood basophils that will ultimately produce the characteristic wheals (Fig. 40-2). The most frequently cited immunologic mechanism of urticaria is a type I hypersensitivity (IgE). Non-IgE-dependent, immune-mediated urticaria may be induced by either type II (cytotoxic, involving antibody and complement) or type III (immune

complex) hypersensitivity reactions. Complement-activated urticaria may involve either immunologic or nonimmunologic mechanisms and may occur through either the classic or the alternative pathway. Urticariogenic materials can induce wheal formation without involving immunologic mechanisms by being ingested, injected, or contacting the animal. Physical agents, including mechanical injury, thermal changes, and solar radiation, may induce urticaria. An example of mechanically induced urticaria is *dermatographism* (whealing after blunt scratch injury to the skin). Local or generalized exposure to heat or cold may induce urticarial lesions in certain individuals.

40.6.3 Clinical Signs and Differential Diagnosis

Wheals range from 1 to 10 cm (0.4 to 4 inches) in diameter and tend to involve the cervical and craniolateral thorax (Fig. 40-3). The animal may or may not be pruritic. Alopecia is not usually a feature of urticaria. The most important factor in distinguishing urticaria from other nodular diseases is that the individual lesions pit with pressure. This is easily demonstrated in the early stages of wheal formation, when the lesions consist primarily of dermal edema. In the later stages, when there is cellular infiltration into the dermis, the pitting is less apparent.

Fig. 40-3 Acute urticaria in a horse caused by an adverse drug reaction.



40.6.4 Diagnosis

Urticaria is usually a clinical diagnosis; the diagnostic dilemma is to determine the *cause* of the urticarial eruption. A skin biopsy not only will lend support to the clinical diagnosis of urticaria, but also may show

evidence of pemphigus foliaceus, dermatophytosis, or vasculitis, Initiation of ectoparasite control, IDT or serologic tests for atopic dermatitis, and feed trials may all be used to determine the underlying disease.[27]

40.6.5 Therapy

Avoiding the allergen/initiating factor or treating the underlying disease is the best therapy. When this is not possible or when the allergens cannot be identified, medical therapy should be used, as described under Atopic Dermatitis.

40.7 MILK ALLERGY

The principal cutaneous manifestation of milk allergy is urticaria and is usually seen in cows during the drying-off period. Increased intramammary pressure presumably causes milk proteins to gain access to the circulation, where they induce a type I hypersensitivity reaction.[30] The disorder is believed to be hereditary and familial, with cattle of the Channel Island breeds demonstrating increased susceptibility.

The urticarial reaction can be localized or generalized. Other clinical signs that may be noted include muscle tremors, respiratory distress, restlessness, ataxia, dullness, and even maniacal behavior. Diagnosis is made by observing an edematous swelling at the site of an intradermal injection of the cow's milk or the milk protein casein diluted 1:1000, in combination with the appropriate clinical signs.[30,31]

Treatment involves the use of antihistamines early in the course of the disease. Prevention requires avoiding milk retention. An affected cow is likely to suffer recurrences of milk allergy, so culling is usually recommended.

40.8 ERYTHEMA MULTIFORME

Erythema multiforme (EM) has been recognized clinically in the horse and in one bull (Fig. 40-4). This is an immunologic reaction in the skin, and programmed keratinocyte cell death (apoptosis) is the prominent change seen on biopsy. The keratinocytes may be killed specifically by killer lymphocytes. The many possible etiologic factors include infectious diseases, drugs, systemic disease, and neoplasia. In the horse, drugs are probably the most frequent inducers of EM, although in many cases an underlying disease is undiagnosed.[32,33] In one bull the EM may have been caused by a pyelonephritis found on necropsy.[34] Clinical lesions are characterized by macules, papules, urticarial lesions, or vesicular bullous lesions. Individual lesions may expand peripherally, leading to the formation of target-like lesions. Scaling and crusting are usually not a feature of equine EM, unless the disease is characterized by erosions or ulcers. Individual lesions can persist for several days, unlike urticarial lesions. Pruritus and pain are variable but usually are not seen. Lesions may occur in association with or after an infection or drug administration. The late Dr. A.A. Stannard of UCD had theorized that reticulated and hyperesthetic leukotrichia may also represent a type of EM in the horse.[33] Interestingly, a similar disease, toxic epidermal necrolysis, has rarely been reported in cattle.[34a]

Fig. 40-4 Erythema multiforme in a horse.

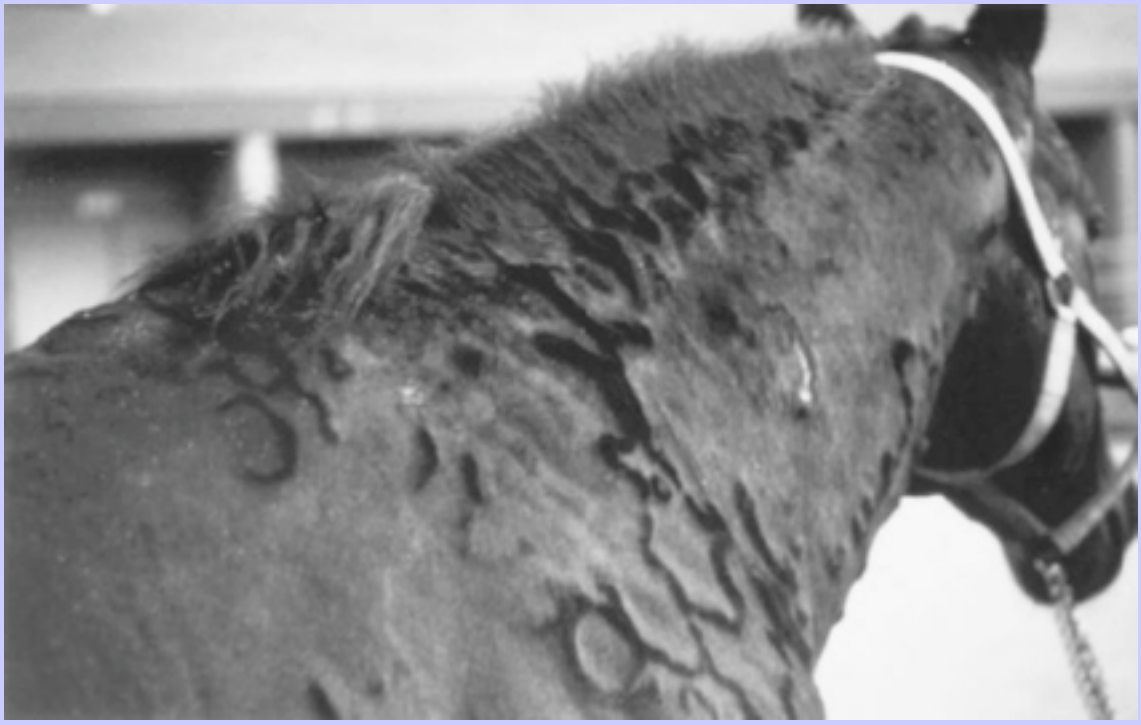


Fig. 40-5 Cutaneous vasculitis in a horse. **A,** Vasculitis involving the forelimbs. **B,** Vasculitis involving the mucous membranes of the inner lip.

Differential diagnoses include urticaria, amyloidosis, and other nodular papular diseases. The diagnosis is made on history, physical examination, and skin biopsies. The histologic changes are distinctive and often include a lichenoid pattern with keratinocyte apoptosis. Vesicular lesions may be present and can include more confluent areas of keratinocyte destruction, with massive spongiosis and subepidermal and intraepidermal edema.

Treatment should be directed toward the underlying cause, if one can be found. A drug eruption should be high on the list, and searching the history for recent drug administration is important. Although some cases of EM are self-limiting and may resolve within 1 to 3 months,[32] corticosteroid treatment as for pemphigus foliaceus may be tried. In my experience, reticulated leukotrichia does *not* resolve spontaneously and does not respond to corticosteroids.

40.9 VASCULITIS

Vasculitis is a histopathologic term that implies the presence of inflammatory changes in the walls of blood vessels, and it is associated with a broad spectrum of disorders. *Cutaneous vasculitis* is recognized in horses and is most often seen as a feature of drug reactions, urticaria, photoactivated/leukocytoclastic vascultitis, or purpura hemorrhagica. Affected vessels may be limited to the skin or may involve other organs, resulting in systemic disease. The cutaneous lesions are characterized by purpura, necrosis, and ulceration, most often affecting the head and extremities (Fig. 40-5).

Pastern leukocytoclastic vasculitis (photoaggravated vasculitis) seems to be more common (if poorly understood) in California and the western United States as a clinical entity. It generally affects mature horses and produces lesions confined to the lower extremities that lack pigment. Lesions are multiple and well demarcated, with the medial and lateral aspects of the pastern the most common sites. Initially, erythema, oozing, crusting, erosions, and ulcerations develop, followed by edema of the affected limb(s). Chronic cases may develop a rough or "warty" surface. The pathogenesis is uncertain; an immune complex etiology has been suggested, and lesions being restricted to nonpigmented areas suggests a role for ultraviolet (UV) radiation. Drug reactions may be a potential cause.[33] A recent report also implicated *Staphylococcus intermedius*.[35]

The differential diagnosis is photosensitization, particularly that caused by contact. The diagnosis is confirmed by skin biopsy, which demonstrates leukocytoclastic vasculitis with vessel wall necrosis and thrombosis involving the small vessels in the superficial dermis. These changes may be difficult to demonstrate.

Treatment involves corticosteroids at relatively high doses (prednisolone at 1 mg/kg q12h or dexamethasone at 0.08 to 0.2 mg/kg q24h) for 2 weeks, then tapered over the next 4 to 6 weeks. Reducing UV light exposure is helpful, either by bandaging affected legs or stabling inside during daylight hours, or both. In some cases, topical corticosteroids (e.g., betamethasone valerate cream 0.1% or triamcinolone spray 0.015%) may enable the horse to be weaned off systemic corticosteroids. I have also used pentoxifylline (8 to 10 mg/kg q12h) as an adjunct treatment in one case, to good effect. Another alternative (but more expensive) is 0.1% tacrolimus ointment q24h (Protopic, Astellas Pharma US). This disease does not usually recur, which downplays sunlight's role in its initiation. These horses are prone to secondary bacterial infections, and a month of antibiotic treatment (usually trimethoprim-sulfa) is often indicated if the horse has fever or if the legs are extensively swollen.

Cutaneous vasculitis seemingly is rare in ruminants; one report in calves describes lesions on the forelegs and ear tips occurring within a month on one farm. Histology showed a fibrinous-necrotic or leukocytoclastic vasculitis. Glucocorticoid (prednisolone) therapy was effective.[36]

Vasculitis and purpura hemorrhagica are discussed in more detail in Chapter 37.

40.10 DRUG ERUPTION

A drug eruption is a cutaneous reaction to any agent that enters the circulation by ingestion, injection, inhalation, or percutaneous absorption. Drug eruptions may or may not be associated with systemic signs. Many drug eruptions are thought to be immunologically mediated hypersensitivity reactions, although on occasion they may occur with the initial administration of a drug and therefore without any prior sensitizing exposure characteristic of an immunologic reaction. Drug eruptions may also occur after years of repeated asymptomatic exposure to a drug, although this is probably less common than formerly supposed. Any medication can cause a drug eruption, but the compounds most frequently incriminated include antibacterial agents (especially semisynthetic penicillins and the sulfas), phenothiazine tranquilizers, nonsteroidal antiinflammatory drugs (NSAIDs) and antipyretics (especially phenylbutazone), local anesthetics, and anticonvulsants. In general, the more recent a drug has been given, the more likely it may be the cause of a skin disease; the clinician should try to determine a temporal association between administration of the drug and the skin disease.

Fig. 40-6 Drug eruption in a horse; note pruritus.

Because drug eruptions can result in a wide variety of cutaneous manifestations, they must be considered in the differential diagnosis of all skin disorders. Certain clinical symptoms are more often associated with drug eruptions. Urticaria and angioedema, diffuse erythema, papular rashes, intense pruritus that is poorly responsive to

corticosteroids (Fig. 40-6), sharply demarcated ulcers secondary to vasculitides, vesicular and bullous eruptions, and photosensitization should arouse clinical suspicion of a drug eruption. Typically, cutaneous lesions are noted 24 to 48 hours after drug administration, although there may be a longer lag interval. The eruption usually subsides within 24 to 48 hours after exposure ceases, although lesions may persist up to 6 months after the offending agent is eliminated.[33]

A diagnosis of drug eruption is based on clinical suspicion associated with an incriminating history of drug administration and by ruling out other possible causes. In a suspected case, all medications should be discontinued. If lifesaving medications are being administered, a chemically unrelated compound with similar pharmacologic effects should be substituted. Administration of corticosteroids may provide some relief, but drug eruptions are variably responsive to corticosteroids. Although development of a cutaneous reaction after readministration of the suspected agent would support a diagnosis of drug eruption, readministration is not advisable because it can be fatal. Future exposure to any implicated compounds and chemically related substances should be avoided.

40.11 CONTACT DERMATITIS

40.11.1 Definition and Etiology

Contact dermatitis is recognized in both horses and ruminants and can be subdivided into irritant and allergic contact dermatitis. *Irritant* contact dermatitis occurs more often and is defined as a cutaneous reaction to an irritating concentration of an offending agent. The substance chemically damages the skin without immunologic mediation. The reaction may occur after a single contact with a strong irritant or after repeated contacts with a milder irritant. *Allergic* contact dermatitis represents a cutaneous reaction in a sensitized animal to a nonirritating concentration of the offending agent. Tissue damage is immunologically mediated by delayed-type hypersensitivity (type IV); thus prior exposure is required to sensitize the skin to the material eliciting the dermatitis.[7,29] It may be difficult to differentiate between the two types of contact dermatitis, and it may not be clinically important. In my experience the vast majority of contact dermatitis cases are iatrogenic, caused by topical products placed on the skin by veterinarians or owners.

40.11.2 Clinical Signs

The clinical lesions associated with allergic and irritant contact dermatitis are very similar. Predisposed areas include the muzzle, the extremities, and the areas contacted by tack. Early lesions include erythema, edema, and vesiculation, which progress to erosions, ulcerations, and crusting and ultimately to lichenification and hyperpigmentation. A gravity-induced drip pattern may be evident when the irritant is a liquid.[37]

40.11.3 Diagnosis

Patch testing is possible but usually impractical. Provocative exposure is the most useful test for diagnosis of contact dermatitis, although it does not reliably distinguish between allergic and irritant contact dermatitis. Provocative exposure requires avoiding contact with all suspected agents for 7 to 10 days to permit clearing of the skin lesions. The patient is then reexposed to these agents on an individual basis at 7- to 10-day intervals while being observed for recurrence of the dermatitis. When a positive reaction is observed, challenge with the suspected agent should be repeated to confirm the diagnosis. The process is time-consuming, requiring patience and cooperation from the owner.

40.11.4 Therapy

An animal with a suspected or confirmed diagnosis of acute or irritant contact dermatitis should be placed in an environment where there is negligible chance of exposure to agents that might have produced the dermatitis. Symptomatic treatment pending spontaneous resolution includes gently washing the affected regions with water. Pentoxifylline at the dose noted earlier for vasculitis may be helpful in horses.

40.12 BACTERIAL DISEASES

STEPHEN D. WHITE

40.13 DERMATOPHILOSIS (STREPTOTHRICOSIS, RAIN SCALD, LUMPY WOOL, STRAWBERRY FOOT ROT)

40.13.1 Definition and Etiology

Dermatophilosis is caused by an actinomycete bacterium, *Dermatophilus congolensis*. The organism is a gram-positive, non-acid-fast, branching, filamentous, aerobic bacteria that divides longitudinally and then transversely to form parallel rows of coccoid zoospores. Dermatophilosis affects horses, cattle, sheep, and goats, as well as a wide host range of other mammals.[38–41]

Three conditions must be present for *Dermatophilus* to manifest itself: a carrier animal, moisture, and skin abrasions. Chronically affected animals are the primary source of infection; however, they become a serious source of infection only when their lesions are moistened, which results in the release of zoospores, the infective stage of the organism. Mechanical transmission of the disease occurs by both biting and nonbiting flies, ticks, and possibly fomites. Because normal healthy skin is quite impervious to infection with *D. congolensis*, some predisposing factor that results in decreased resistance of the skin is necessary for infection to occur, especially prolonged wetting of the skin by rain. The organism has only recently been isolated from the environment of affected animals. Although the distribution is worldwide, the frequency of occurrence of dermatophilosis varies with geographic location. There is no apparent age, breed, or gender predilection.

Fig. 40-7 Dermatophilosis *(Dermatophilus congolensis)*. **A,** Horse with suppurative crusts and matted hair on the back. **B,** Scaling and crusting over withers and neck of a bovine.

40.13.2 Clinical Signs

Dermatophilosis is usually seen during the fall and winter months, with the dorsal surface of the animal most often affected (Fig. 40-7). In horses, this association with the wetter months of the year has led to the term “rain scald.” Occasionally the lesions involve the lower extremities when animals are kept in wet pastures (“dew poisoning”) or if horses are left in the stall while the stall is cleaned with high-pressure water hoses. In the early stages of disease the lesions can be felt easier than they can be seen. Thick crusts can be palpated under the hair coat. Removing the crusts and attached hair exposes a pink, moist skin surface, with both the removed hair and the exposed skin assuming a paintbrush shape. The undersurface of the crusts are usually concave, with the roots of the hairs protruding. In cattle and goats the older term “cutaneous streptothricosis” is sometimes used. In sheep the condition is referred to as “lumpy wool” or “mycotic dermatitis” when wooled areas are affected and “strawberry foot rot” when the distal extremities are involved.

Body areas predisposed to infection include those that are most susceptible to maceration and trauma. The distal extremities, muzzle, and entire length of the dorsum are frequently the initial sites of infection. Nonpigmented skin is also reported to be more susceptible to infection. Horses develop lesions in areas rubbed by tack, and cattle often have involvement of the udder and scrotum. Goat kids reportedly have a tendency to develop lesions on the pinnae and under the surface of the tail. Sheep may develop a form of dermatophilosis that begins as an encrusted, proliferative dermatitis at the coronet region; removal of the external crusts reveals a pink-red granulation bed that resembles the surface of a strawberry. Lesions can extend from the hoof to the hock, and with loss of the crusts, ulceration occurs. Under appropriate conditions, dermatophilosis can become generalized.

40.13.3 Diagnosis

Diagnosis is made by demonstrating the “railroad track” cocci on impression smears. A portion of one of the crusts should be minced and mixed with a few drops of sterile water on a glass slide, Gram stained, and examined microscopically. Alternatively, bacterial culture or histopathology may be used for diagnosis, particularly in chronic cases. A thick crust composed of alternating layers of parakeratotic stratum corneum, dried serum, and degenerating neutrophils is the most characteristic change. A superficial folliculitis may be a prominent feature of the disease.[38] In Gram-stained sections the branching, filamentous organisms can be observed in the crusts and in the follicles.

40.13.4 Therapy

The animal should be removed from the wet environment, if possible. Careful removal of possibly painful crusts, washing with iodophors or lime sulfur, and administration of antibiotics (for horses, 22,000 mg/kg procaine penicillin G intramuscularly twice daily, or 30 mg/kg trimethoprim-sulfa orally twice daily) for 7 to 10 days.[41] Long-acting oxytetracycline given as a single 20-mg/kg intramuscular dose has been reported to be effective for bovine and ovine dermatophilosis. The crusts are important in contagion, so these should be disposed of rather than brushed to the ground.

40.14 FOLLICULITIS/FURUNCULOSIS AND IMPETIGO

40.14.1 Definition and Etiology

Bacterial *folliculitis* (superficial pyoderma) is defined as inflammation of the hair follicles secondary to a bacterial infection. *Furunculosis* is the term used to describe a follicular infection that breaks through the follicular wall ("boil"). Bacterial infection that causes subcorneal pustules but does not involve the hair follicles is called *impetigo*. Folliculitis and furunculosis are often seen in horses[28,38,41] and goats[40] but are an uncommon problem in cattle and sheep. Impetigo is relatively common in cattle and goats.

Bacterial folliculitis is usually caused by a coagulase-positive *Staphylococcus* species. Both *S. aureus* and *S. intermedius* have been isolated.[28,42] In one study in horses, *S. aureus* accounted for twice as many isolates as *S. intermedius;* the same study isolated some strains of *S. hyicus* as well.[43] Many isolates are resistant to penicillin G.[43] Occurrence of pyoderma has been linked to poor nutrition and husbandry in some cases.[44]

40.14.2 Clinical Signs

Clinical signs of staphylococcal pyoderma are most often crusts, usually in a circular pattern suggestive of dermatophytosis (this may be the reason that equine pyoderma is underdiagnosed), epidermal collarettes (circular skin lesions with an exfoliative border as seen in dogs with superficial pyoderma), or encrusted papules similar to the miliary dermatitis reaction pattern in cats.[28] These infections tend to vary in intensity of pruritus. Histology often shows folliculitis and furunculosis, but bacterial colonies are not always seen. A truncal form of bacterial folliculitis (contagious acne, contagious pustular dermatitis, Canadian horsepox) is often associated with poor grooming and trauma from tack and saddle, warm wet weather, and heavy work. It is painful and interferes with working and riding. It is usually caused by a coagulase-positive *Staphylococcus* species but may also result from *Corynebacterium pseudotuberculosis*[45] (more often a cause of deep pyoderma, as discussed later). In horses, folliculitis often develops in the saddle and lumbar region, particularly in the summer. The affected area initially may be swollen and sensitive, followed by formation of follicular papules and pustules. These may become confluent or may rupture, forming plaques and crusts. Deep pyoderma followed by ulceration may develop over large areas of the body, especially the neck, sides of the thorax, inner surface of the thighs, and prepuce.

A pastern bacterial infection (pastern folliculitis) is often seen. Again, the causative agent is usually a coagulase-positive *Staphylococcus* species. As with most "primary pyodermas," the mechanism by which the organism gains its foothold is unknown; it is not contagion or poor sanitary conditions. The lesions are usually limited to the posterior aspect of the pastern and fetlock regions; one or more limbs may be involved. The initial lesions consist of papules and pustules. If left untreated, the lesions coalesce and may produce large areas of ulceration and suppuration, which may be quite painful. The disease is usually not associated with systemic signs, and the general health of the horse is not affected.

A relatively uncommon nodular disease termed *botryomycosis* mimics actinomycosis or a deep fungal infection but is most often caused by *Staphylococcus* species in the horse. These may require surgical excision as well as long-term antibiotics.

40.14.3 Public Health Considerations

In a 2000 study, methicillin-resistant, coagulase-negative staphylococcal species were cultured from healthy horses in Japan; the authors concluded, "These organisms must be considered a potential threat to horses and veterinarians who care for them."[46] In a 2006 study from the Netherlands, methicillin-resistant coagulase-negative staphylococci were found frequently.[47] The organism was usually *Staphylococcus sciuri*, as opposed to *S. epidermidis,* which was found in the humans in close contact with these horses. No methicillin-resistant *Staphylococcus aureus* (MRSA) was found in healthy horses.

In contrast, a single strain of MRSA was isolated from *both* humans (13%) and horses (4.7%) on horse farms in Canada and New York state.[48] In looking at horses admitted to a university teaching hospital (Ontario Veterinary College), MRSA was isolated from 120 (5.3%) of 2283 horses. Of these 120 horses, 50.8% were positive at admission, and clinical infections attributable to MRSA were present or developed in 14 animals. Horses colonized at admission were more likely to develop clinical MRSA infection. Administration of ceftiofur or aminoglycosides during hospitalization was the only risk factor associated with nosocomial MRSA colonization. Another strain of MRSA was isolated from a small number of horses at the Veterinary University, Vienna, Austria.[49]

Of most concern is the finding of humans reporting skin lesions after contact with a community MRSA-positive affected foal, despite short-term contact with standard protective barriers. The isolates from the foal were indistinguishable from those affecting humans.[50]

40.14.4 Therapy

The antibiotic usually used for bacterial skin infections in the horse is trimethoprim-sulfamethoxazole (TMS) orally (PO, 30 mg/kg q12h for 2 to 6 weeks, longer for deep infections).[7,28] Interestingly, dosing intervals for intravenous (IV) administration of TMS in horses may not be appropriate for use in donkeys or mules. Donkeys eliminate the drugs rapidly compared with horses.[51] In cases of staphylococcal resistance to TMS, enrofloxacin or doxycycline may be used. Doxycycline is less expensive, but is associated with a higher incidence of colic. Dosage is usually 10mg/kg q12h. Off-label use of oral enrofloxacin formulations for poultry, ruminants, or swine has been suggested; a dose for the poultry formulation has been suggested as 7.5 mg/kg PO once daily. The formulation for poultry may be used; the dose is 7.5 mg/kg PO once daily. Use of enrofloxacin in young horses (<2 years old) should be avoided because of concerns about damage to the articular cartilage.[52] A recent report of the usage of an oral gel formulation of enrofloxacin (100 mg/mL of gel) showed good clinical efficacy for infections in several organs; however, almost one-third of the horses had some diarrhea, and 10% had oral lesions.[53] The authors believed that this latter side effect could be overcome with a tap water rinse of the oral cavity after administration. Interestingly, enrofloxacin binds to melanin in equine hair, although the clinical implication is unknown.[54] Ceftiofur sodium 2.2 mg/kg, q12-24h, IM or IV, may also be used for pyoderma in horses, although its usefulness over a long period is limited by its parenteral route. In one report of 15 horses, vancomycin was used, alone or in combination with an aminoglycoside, to treat MRSA and enterococcal infections. The average vancomycin dosage was 7.5 mg/kg q8h IV over 30 minutes. The antibiotic, alone or in combination with an aminoglycoside, was safe and effective. Because of the problems with emerging resistance, the authors recommended vancomycin use in horses be limited to cases in which culture and susceptibility indicate effectiveness and no reasonable alternative treatment exists.[55]

For localized lesions, mupirocin ointment 2% or silver sulfadiazine cream (Silvadene) may be effective. As shampoos, ethyl lactate (Etiderm, VIRBAC, Fort Worth, Texas) or chlorhexidine (2% to 4%) are helpful.

Pyoderma in ruminants has not been studied as much as in horses. In goats, lesions (often pustules that progress to crusts) usually begin on the udder and spread to the abdomen, thigh, perineum, and face. Pruritus is variable. Stress from parturition is also an important predisposing factor in goats. In sheep a generalized, staphylococcal, scalded skin—like disease has been reported in lambs.[56] In addition, staphylococcal infections in association with *Psoroptes ovis* infestation have been noted.[57,58]

In cattle, furunculosis caused by *C. pseudotuberculosis* manifests as a locally extensive, raised, raw lesion that is frequently hemorrhagic. The lesions are almost constantly covered with a serosanguineous exudate, and palpation of the lesions usually elicits a pain response. Treatment is similar to treatment of dermatophilosis, taking into consideration culture and susceptibility results, as well as withdrawal times for food animals.

40.15 EQUINE STAPHYLOCOCCAL CELLULITIS

Cellulitis is a severe, deep, suppurative process in which a poorly defined area of infection tends to dissect through tissue planes. Although many organisms are capable of producing cellulitis, staphylococcal cellulitis has been recognized as a specific disease entity in thoroughbred racehorses.[59] Coagulase-positive staphylococci have been isolated from all reported cases, and when speciated, the isolates were classified as *Staphylococcus aureus*.[60] Other studies of pathogenic *Staphylococcus* species from horses have suggested that *S. aureus* and *S. intermedius* are the major cutaneous pathogens,[60,61] with no significant difference in their susceptibility patterns.[60] In a recent retrospective study of limb cellulitis in 44 horses, coagulase-positive *Staphylococcus* spp were cultured from 33 of 36 horses from which specimens were obtained. Horses that were febrile at admission or that developed laminitis were significantly less likely to survive.[61a]

The cause of staphylococcal cellulitis is uncertain. Management practices may be associated with the condition because bathing, grooming devices, and handlers can be a source of the organism.[61]

The initial symptom is acute swelling and lameness that involves one or more limbs. Lesions progress rapidly by dissection along tissue planes. The overlying skin becomes devitalized and frequently sloughs. Accompanying systemic signs include increased rectal temperature and heart rate. Laminitis of either the affected or the contralateral limbs, osteomyelitis, and bacteremia are possible sequelae.[59] Diagnosis is based on the results of bacterial culture and biopsies for routine histopathology.

Treatment must be aggressive and initiated early in the course of the disease. Pending the results of bacterial culture and sensitivity, treatment should include broad-spectrum antibiotics such as potassium penicillin G and gentamicin sulfate or TMS. To decrease edema, promote weight bearing, and reduce the chance of laminitis, therapy should include NSAIDs, hydrotherapy, and support wraps.[59] The prognosis for complete recovery is guarded.

40.16 EQUINE *CORYNEBACTERIUM PSEUDOTUBERCULOSIS* CELLULITIS

Unlike equine staphylococcal cellulitis, solitary or multiple abscesses or nodules with many draining tracts that progress to diffuse cellulitis are often caused by *Corynebacterium pseudotuberculosis*; when it affects the pectoral region, it is termed “pigeon fever” in the United States. This type of deep *Corynebacterium* infection may occur

where caseous lymphadenitis is common in sheep, although proximity to sheep is not a requirement, and it also may be seen seasonally when insect population and activity are maximal. Insect vectors seem probable, especially stable, horn, and house flies.[62] The draining nodules or abscesses are especially common in the pectoral region and occasionally affect the face, neck, axilla, groin, and limbs; they begin deep and enlarge, often with much edema, and rupture in 1 to 4 weeks, discharging viscid, creamy pus, a major source of contamination. Abscesses most often rupture externally.

Diagnosis is by clinical signs, with the infection readily identified by bacterial culture of aspirate samples from abscesses. The synergistic hemolysis inhibition test is useful for diagnosis of internal abscesses but is unreliable for external abscesses.[63]

Treatment depends on location. For example, if the abscess is in the axilla and thus is painful on movement or prevents locomotion, establishment of drainage is important, and antibiotics are indicated. The antibiotics most often used are procaine penicillin (20,000 to 50,000 IU/kg/day) with rifampin (3 to 5 mg/kg PO); alternatively, TMS (30 mg/kg q12h) may be used.[64] Treatment with TMS and rifampin concurrently may lead to a greater incidence of colitis and should be avoided. If the decision is made to use antibiotics but drainage cannot be easily established (e.g., axillary abscess, with owner unwilling to allow veterinarian to use trocar and drain), the antibiotics *must* be used for a minimum of 1 month. If the abscess is solitary and not causing pain or fever, antibiotics are usually not necessary, but bringing the abscess to a head with hot packs or heat-inducing agents (ichthymol) is important. Once an abscess has drained, gentle cleaning with tamed iodines or chlorhexidine is indicated.

40.17 PAPILLOMATOUS DIGITAL DERMATITIS (DIGITAL DERMATITIS, FOOT WARTS, HEEL WARTS, HAIRY FOOT WARTS, MORTELLARO's DISEASE, STRAWBERRY HEEL WARTS)

STEVEN L. BERRY

Papillomatous digital dermatitis (PDD) of cattle is an infectious, contagious dermatitis of the digital skin of cattle. It is primarily a disease of housed dairy cattle. PDD was first described in Italy in 1974 and in New York in 1980. During the early 1990s the reported first observations of PDD increased dramatically in the United States, and this disease is a major cause of lameness in dairy cattle in many countries.[65,66] Financial losses are from reduced milk production, reduced reproductive efficiency, costs of treatment, and premature culling. European and U.S. studies estimate the cost per case to be approximately $130. Prevalence in endemically infected herds is typically 10% to 60%.

1314 1315

40.17.1 Clinical Signs

About 80% of PDD lesions occur on the plantar aspect of the hindfoot, immediately proximal to the heel bulbs and adjacent to or extending into the interdigital space.[65] Less common sites for lesions are the plantar aspect of a forefoot and the dorsal aspect of any foot. Multiple lesions may exist on a single animal, even on a single foot, but lesions are confined to the digital skin and have not been reported to occur above the level of the dewclaws.[65]

The gross appearance of the lesions and the predilection for hindlimbs and skin-horn junctions, especially those bordering the heel bulbs and interdigital space, distinguish this disease from other bovine dermatitides. Lesions

are most often 2 to 6 cm (0.8 to 2.4 inches) across at their greatest dimension, are circular or oval, and have clearly demarcated, raised borders.[65,67] Lesion borders are often surrounded by hairs that are two to three times normal length. Lesion surfaces may have filiform papillae varying in length from 1 mm to 3 cm (1.2 inches) and 0.5 to 1 mm in diameter, thus the name "hairy foot warts." Lesions lacking the filiform papillae ("hairs") may have a granular surface. Lesions vary in color and appearance. Washed surfaces are generally very painful and either red and granular or composites of white, yellow, gray, brown, or black papillary areas with red, granular areas interspersed.[65] The lesions bleed easily if traumatized. When PDD lesions develop in the interdigital space, they frequently occur on a preexisting fibroma.

The lesions slowly enlarge and become raised (papillomatous) masses 2 to 6 cm in diameter that are red, gray, or black and oval, spherical, or U shaped. Proliferative or papillomatous lesions are seen less often in Europe than in the United States and are less common on dairies with a consistent treatment and control program.

A foul odor may be present and appears to be caused by secondary bacterial growth in the exudate covering the PDD lesion. Swelling of the pastern and fetlock regions is not present in uncomplicated cases. Lameness is a herd characteristic on dairies where PDD has a high prevalence but is an inconsistent finding on individual infected cattle and is not consistently related to lesion size or maturity.[68] If PDD lesions remain untreated, the claws of feet with plantar or palmar lesions may develop a clubbed appearance because the cow prefers to bear weight on (and wear down) the toes.[65]

40.17.2 Differential Diagnoses

Differential diagnoses for an individual case of PDD include interdigital necrobacillosis (foot rot, "foul in the foot," or interdigital phlegmon), interdigital hyperplasia (corns or interdigital fibroma), interdigital dermatitis, and traumatic injury with granulation tissue. For herd problems of lameness localized to the digit, differential diagnoses should include PDD, interdigital necrobacillosis, interdigital dermatitis, laminitis, excessive sole wear from caustic or abrasive flooring, and improper claw trimming. If signs of polysystemic disease exist, coronitis from viral diseases (e.g., bovine viral diarrhea) should also be considered.

40.17.3 Epidemiology

Once introduced into a herd, PDD spreads rapidly within adult cows, often affecting the majority of adults within the first year of infection.[65] When established in a herd, lameness is most often seen in first- and second-lactation cows.[65,67] Lesions are typically present in a proportion of older cows, but lameness is less apparent than in the younger cows. Bulls and yearling heifers may also be affected but usually comprise a small fraction of clinical cases. In California the disease appears to be most severe during the spring and summer months,[65] whereas in Europe it is most severe in the winter months. Free-stall herds are more often affected than stanchion (tie-stall) herds, probably because of better foot hygiene in the stanchions. Cattle confined to pasture are rarely affected,[69] but the disease is emerging in some South American countries with wet pastures during part of the year. PDD is almost exclusively seen in dairy cattle, with Holsteins more likely to be affected than Jersey or dual-purpose breeds.[69,70] Eradication of PDD from an endemically infected herd is unlikely.

Retrospective epidemiologic studies indicated that two risk factors are significant in high-prevalence herds: muddy or wet conditions and purchasing replacement cattle from off premises.[69,71,72] Other risk factors identified were the use of outside hoof trimmers and not washing hoof-trimming equipment between cows.[72]

Attempts to transmit the disease experimentally were successful when scrapings from active lesions were applied to the feet of calves subjected to constant moisture and low oxygen tension. Constant moisture and low oxygen tension are present on confinement dairies if manure management and hygiene are not adequate. Poor free-stall or bedding area management will exacerbate the problem by forcing cows to stand in manure slurry for longer periods and will not allow the feet of cattle to dry out periodically.

40.17.4 Pathogenesis

Numerous obligate anaerobic organisms have been associated with PDD.[73] Spirochetes from the genus *Treponema* have been identified most consistently.[74–78] During experimental transmission studies, *Treponema* species are the first organisms to appear, comprise the bulk of the colonizing bacterial mat found on active lesions, and are the organisms that invade the epidermis and dermis.[76] These spirochetes also produce a humoral response in cows with active lesions.[65,78] PDD lesions show gross and histologic similarities to viral papillomas; however, bovine papillomavirus has not been found.[65]

Current evidence indicates that PDD is multifactorial, involving environmental, microbial, host, and management factors. Factors such as rough flooring; poor drainage; accumulation of feces and urine on floors; dirty, wet, or uncomfortable bedding areas; and overcrowding have an adverse effect on digital skin health and could increase the risk of PDD. The mode of transmission between cows and between herds is currently unclear, although one study found concurrent spirochetal infection of feet and colon in cattle.[79] Clinically and subclinically affected cows and fomites such as foot-trimming instruments, livestock trailers, and farm equipment may be sources of infection for naive herds.

A California study found that antibodies against two antigenically distinct spirochetes were increased on dairies with PDD compared with PDD-free dairies.[78] Also, cattle with PDD on a high-prevalence dairy were much more likely to have antibodies to the spirochetes than were cattle without lesions on the same dairy.[78] There was no cross-reactivity between the two spirochetes or to other spirochetal diseases of cattle.[78] The concentration of clinical disease in the younger animals of an endemically infected herd suggests that some degree of immunity may develop in older cows. Nonetheless, chronic and recurrent cases in otherwise healthy adult cattle have been reported, and immunity to PDD, if it does develop, may be incomplete or temporary. One study found high recurrence or new lesions 7 to 12 weeks after successful treatment.[65] Spontaneous regression of lesions and resolution of lameness have also been observed but appear to be rare.

1315 1316

40.17.5 Pathologic Findings

Histopathologic criteria to establish a diagnosis of PDD are as follows[65]:

- Circumscribed plaque of eroded acanthotic epidermis attended by parakeratotic papillomatous proliferation profusely colonized by spirochete-dominant bacterial flora.
- Loss of stratum granulosum.
- Invasion of stratum spinosum by spirochetes.
- Infiltration of neutrophils, plasma cells, lymphocytes, and eosinophils in the dermis.

If performed, biopsies should be full-thickness 6-mm punch biopsies, washed off with sterile saline, and placed in buffered formalin. Histopathology is helpful to confirm a diagnosis of PDD but is not necessary because lesions have such a characteristic appearance and location.

Preliminary results of a biopsy study on treatment and recurrence of PDD indicate that the gross visual and histopathologic diagnoses were in agreement for active lesions before treatment. Histopathology on day 28 after treatment with lincomycin or oxytetracycline, however, found a high percentage (55%) of lesions that visually appeared to be healed but still had microscopic evidence of infection.[80] It could not be determined if lesions were incompletely healed or recurrent infections.

40.17.6 Treatment and Prevention

The most common treatments for PDD involve the use of topical antibiotics.[68,81] There are limited reports of nonantibiotic products being efficacious, although research and development continue. Currently, no antibiotics are labeled for treatment of PDD in the United States; therefore, adherence to extralabel drug use regulations is imperative.

The most common treatment for PDD in the United States is topical oxytetracycline or lincomycin used as a spray or applied with a bandage. For topical spray treatments, oxytetracycline or lincomycin are mixed with deionized or distilled water in a 2- to 4-L agricultural sprayer (25 g/L oxytetracycline, 8 g/L lincomycin) and applied directly to the heels of PDD-affected cattle once daily for 5 to 10 days. Recurrence is sufficiently common that topical treatments need to be repeated every 45 to 60 days on affected cattle to control the disease. No antibiotic residue violations have been reported resulting from topical application of antibiotics.[82] Efficacy from parenteral antibiotics has been inconsistent.

Footbaths are often used on dairies to control PDD and other infectious causes of lameness, although most footbath products have not been rigorously evaluated.[68] Products used include antibiotics, copper or zinc sulfate (5%), formalin (5%), and various proprietary products. On large dairies, footbaths may be more effective at controlling PDD when the disease is at a low prevalence (<10%). When the disease has a high prevalence, individual topical treatment is probably more efficacious at reducing the prevalence. The efficacy of footbaths is reduced if feces and debris are allowed to accumulate in the treatment solution. This problem can be limited by placing two footbaths in tandem, with the first containing water or a mild detergent solution for cleaning the feet and the second containing the antiseptic solution. The footbath solution should be changed every 150 to 300 cow passages, depending on soiling. Footbaths should be a minimum of 8 feet long and 2 to 3 feet wide, with a depth of 5 to 6 inches so that cows have to place all four feet in the solution as they walk through. The baths should be covered to limit dilution by rain and should be located in an exit alley off of the milking parlor to avoid splash contamination of the teat ends before milking. Additional footbaths can be placed in other locations to treat bulls, dry cows, and heifers. Treatments should occur every 2 to 7 days depending on response on the individual dairy. Laws regarding the use and disposal of certain chemicals, as well as *where* on the dairy such medications can be used, often vary among locales. Consultation with local regulatory agencies is prudent before initiation of a control program on a dairy.

The efficacious use of footbaths on dairies signals major husbandry problems on dairies because the environmental and hygiene problems are often not addressed.[83] Improvement of stall, corral, and alley hygiene; provision of dry and comfortable bedding; reduction of stocking rate; and improved ventilation to allow drying of stalls and alleys may result in reduction of the incidence or severity of clinical cases. Claw-trimming

equipment, mobile tilt tables, and livestock trailers should be thoroughly cleaned and disinfected to prevent potential transmission of the agent(s) of PDD between dairies.

A *Treponema* bacterin was developed, tested, and licensed for use in the United States. A blind field study where half the lactating cows were vaccinated and half received a placebo vaccine (no *Treponema*) did not find a prophylactic or therapeutic effect of the vaccine.[84]

40.18 INTERDIGITAL DERMATITIS

Interdigital dermatitis (ID) is acute or chronic inflammation of the interdigital skin that usually does not cause lameness. Inflammation is confined to the epidermis. Diffuse epidermal erosion in the interdigital cleft may be seen in early cases. More chronic cases show hyperkeratosis, which creates a roughened appearance to the interdigital skin and dorsal and palmar commissural skin folds. A malodorous, gray, serous exudate may be present, and there is mild sensitivity to pressure. This condition is frequently accompanied by cracks in the heel *(heel horn erosion)*, with potential underrunning of the heel horn, and some researchers consider ID and heel horn erosion to be the same disease (IDHE). When severe, IDHE will cause lameness.

Dichelobacter nodosus and *Fusobacterium necrophorum* may be primary or contributory pathogens for ID. Several investigators have speculated that ID and PDD are forms of the same disease complex. Both share several histologic characteristics, including spirochetal involvement, and both can be successfully treated and prevented with the same topical antibiotics or footbaths. However, ID can persist on dairies that practice regular foot bathing because the causative organisms may survive within deep heel cracks that are not permeated by footbath solutions. During claw trimming, heel cracks must be trimmed away to allow for exposure.

Interdigital dermatitis differs from interdigital necrobacillosis (foot rot), in which infection extends into the dermis, leading to fissure formation, infection of deeper structures, and cellulitis of the pastern and fetlock regions.

40.20 PAPILLOMAS (WARTS, FIBROPAPILLOMAS)

40.20.1 Definition and Etiology

1316
1317

Cutaneous papillomas or warts occur (in decreasing order of frequency) in cattle, horses, goats, and sheep.[85–88] The growths usually occur in young animals,[88] as well as on teats of mature cattle and goats, and are white, tan, or gray, firm protruding masses with a dry, horny surface. They vary in size from 1 to 500 mm and may be single or multiple. Species-specific papillomaviruses (subgroup of papovavirus) are responsible for causing warts. It is now accepted that parts of the bovine papillomavirus (BPV) genome are found in naturally occurring equine sarcoids.[89] There are at least 10 BPV strains, designated BPV-1 through BPV-10 (Table 40-1),[90] and there are probably more. Only one strain of virus is currently recognized in horses, goats, and sheep, but little research on papillomas has been done in these species, and two horse and two goat strains are likely.

Table 40-1 Distribution and Appearance of Bovine Warts by Type of Virus

Virus Strain	Usual Site	Appearance	Comments
BPV-1	Nose, teats, glans penis	Filamentous or frondlike	Can prevent breeding when on penis
BPV-2	Head, neck, brisket, occasionally alimentary tract	Pedunculated or broad-based mass	Most common typical warts
BPV-3	Atypical warts, head, neck, possibly interdigital*	Nonpedunculated protruding growths, delicate fronds with hair between	Persist for years
BPV-4	Alimentary tract, urinary bladder	Pedunculated mass	See Chapters 32 and Chapter 34
BPV-5	Teat	Smooth, white	Persist for years; other types may also occur on teats
BPV-6	Teat	Round and either flat or frondlike	Similar in appearance to BPV-1 when frondlike

Modified from Hunt E: *Vet Clin North Am Large Anim Pract* 6:163, 1984.

BPV, Bovine papillomavirus.

* Suspected, but BPV-3 not yet isolated from interdigital warts. Some authors speculate that interdigital warts may be caused by yet another new BPV strain.

40.20.2 Clinical Signs

Warts are usually small, benign growths that appear on young animals under 2 years of age, persist for 3 to 12 months, and then spontaneously regress without causing clinical signs (other than a blemish). In cattle, warts on the teats, penis, or interdigital skin[91] or in the alimentary tract may produce clinical signs of pain or occlusion. Warts usually develop in the ears of young cattle after tagging or tattooing, especially if instruments are not disinfected between individuals; these are not age related. Teat warts also predispose to environmental mastitis. Occasionally, individuals with (presumed) defective cellular immunity may develop multiple, extremely large warts that may result in weight loss.

In horses, warts on the face are rather common but rarely cause a significant problem (Fig. 40-8). The previously reported congenital wart in young horses has now been more properly termed a hamartomatous lesion (epidermal nevus) and has been shown not to be virus induced.[92]

Fig. 40-8 Typical warts (papillomas) on the nose of a yearling horse.

Warts are relatively rare in goats. They occur mainly on teats and may spread throughout the herd. A 1936 report described a herd outbreak involving the head, neck, shoulders, and forelegs in milking goats.[93] Does without adequate pigmentation on the udder develop persistent mammary gland warts that may undergo transformation to become squamous cell carcinomas.[94] There are probably at least two different strains of goat papilloma virus (head/neck and mammary).

Warts are rare in sheep but may occur on the face or legs. Differential diagnosis in sheep and goats includes contagious ecthyma (orf), ulcerative dermatosis, dermatophilosis, and sheeppox and goatpox.

40.20.3 Treatment and Control

Small warts can be crushed, pinched off, or surgically removed. Cryosurgery can be used on larger warts. Many regress spontaneously within a few months, even without treatment.

When show animals are involved or when animals have multiple large papillomas, tissue can be removed and made into crude autogenous vaccine (2 mL intradermally three times weekly) by homogenizing, grinding, freeze-thawing twice, filtering, and killing virus with 0.5% formalin. Autogenous wart vaccines are variable in their efficacy, as are commercial vaccines.[95–97] The latter rarely seem to result in effective regression of existing warts, but may prevent the development of new lesions if the same BPV strain is involved. Autogenous

vaccines are capable of preventing new lesions caused by the same BPV strain in a herd. There is no indication that cattle vaccines have any efficacy in other species. No wart vaccines for horses, sheep, or goats are currently marketed.

Because the viruses can be directly or fomite transmitted, prevention involves isolation, preventing animals from rubbing on each other, and not sharing halters, brushes, and other equipment. Dipping of dehorning, tagging, and tattooing instruments in a viricidal solution between animals will also slow spread of the virus.

40.21 AURAL PLAQUES

Aural plaques may be a form of viral papilloma that often affects the inner pinna (Fig. 40-9). Nonpruritic, these plaques may also occur on the genitalia and mammary glands. The color varies from pink to grayish-white. 1317
Plaques do not resolve spontaneously, as do the "classic" papillomas seen in young horses. Biopsy or "shaving 1318
off" aural papillomas may stimulate reduction or resolution of the masses, although in some horses, this may only be temporary (6 to 12 months). This has been theorized to be due to the release of "papilloma antigens" into the blood stream during the surgical procedure, prompting an immune response against the tumor. Imiquimod (Aldara, 3M, Minneapolis), a nonsteroidal local immune response—modifier cream, has been helpful in some cases, used three times weekly, every other week, for 2 to 4 months. Owners should wear gloves and should be forewarned that there is frequently an impressive inflammatory reaction to the cream in the initial weeks of treatment.

Fig. 40-9 Aural plaques on the inner surface of the pinna of the ear in a horse.

A papillomavirus has been demonstrated in aural plaques on electron microscopy and with immunohistochemical techniques.[98]

40.22 PSEUDOCOWPOX
